Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

The 24TH Edition of *Goldman's Cecil Medicine* symbolizes a time of extraordinary advances in medicine and in technological innovations for the dissemination of information. This textbook and its associated electronic products incorporate the latest medical knowledge in formats that are designed to appeal to learners who prefer to access information in a variety of ways.

The contents of *Cecil* have remained true to the tradition of a comprehensive textbook of medicine that carefully explains the *why* (the underlying normal physiology and pathophysiology of disease, now at the cellular and molecular as well as the organ level) and the *how* (now frequently based on Grade A evidence from randomized controlled trials). Descriptions of physiology and pathophysiology include the latest genetic advances in a practical format that strives to be useful to the nonexpert. Medicine has entered an era when the acuity of illness and the limited time available to evaluate a patient have diminished the ability of physicians to satisfy their intellectual curiosity. As a result, the acquisition of information, quite easily achieved in this era, is often confused with knowledge. We have attempted to counteract this tendency with a textbook that not only informs but also stimulates new questions and gives a glimpse of the future path to new knowledge. Grade A evidence is specifically highlighted in the text and referenced at the end of each chapter. In addition to the information provided in the textbook, the Cecil website supplies expanded content and functionality. In many cases, the full articles referenced in each chapter can be accessed from the Cecil website. The website is also continuously updated to incorporate subsequent Grade A information, other evidence, and new discoveries.

The sections for each organ system begin with a chapter that summarizes an approach to patients with key symptoms, signs, or laboratory abnormalities associated with dysfunction of that organ system. As summarized in Table 1-1, the text specifically provides clear, concise information regarding how a physician should approach more than 100 common symptoms, signs, and laboratory abnormalities, usually with a flow diagram, a table, or both for easy reference. In this way, *Cecil* remains a comprehensive text to guide diagnosis and therapy, not only for patients with suspected or known diseases but also for patients who may have undiagnosed abnormalities that require an initial evaluation.

Just as each edition brings new authors, it also reminds us of our gratitude to past editors and authors. Previous editors of *Cecil Medicine* include a short but remarkably distinguished group of leaders of American medicine: Russell Cecil, Paul Beeson, Walsh McDermott, James Wyngaarden, Lloyd H. Smith, Jr., Fred Plum, J. Claude Bennett, and Dennis Ausiello. As we welcome new associate editors—Wendy Levinson, Donald W. Landry, Anil Rustgi, and W. Michael Scheld—we also express our appreciation to Nicholas LaRusso and other associate editors from the previous editions on whose foundation we have built. Our returning associate editors—William P. Arend, James O. Armitage, David Clemmons, Jeffrey M. Drazen, and Robert C. Griggs—continue to make critical contributions to the selection of authors and the review and approval of all manuscripts. The editors, however, are fully responsible for the book as well as the integration among chapters.

The tradition of *Cecil Medicine* is that all chapters are written by distinguished experts in each field. We are also most grateful for the editorial assistance in New York of Theresa Considine and Silva Sergenian. These individuals and others in our offices have shown extraordinary dedication and equanimity in working with authors and editors to manage the unending flow of manuscripts, figures, and permissions. We also thank Faten Aberra, Reza Akari, Robert C. Brunham, Ivan Ciric, Seema Daulat, Gregory F. Erikson, Kevin Ghassemi, Jason H. Huang, Caron Jacobson, Lisa Kachnic, Bryan T. Kelly, Karen Krok, Heather Lehman, Keiron Leslie, Luis Marcos, Michael Overman, Eric Padron, Bianca Maria Piraccini, Don W. Powell, Katy Ralston, James M. Swain, Tania Thomas, Kirsten Tillisch, Ali Turabi, Mark Whiteford, and Y. Joseph Woo, who contributed to various chapters. At Elsevier, we are most indebted to Dolores Meloni and Linda McKinley, and also thank Cathy Carroll, Taylor Ball, Virginia Wilson, Linda Van Pelt, Suzanne Fannin, and Steve Stave, who have been critical to the planning and production process under the direction of Mary Gatsch. Many of the clinical photographs were supplied by Charles D. Forbes and William F. Jackson, authors of *Color Atlas and Text of Clinical Medicine*, Third Edition, published in 2003 by Elsevier Science Ltd. We thank them for graciously permitting us to include their pictures in our book. We have been exposed to remarkable physicians in our lifetimes and would like to acknowledge the mentorship and support of several of those who exemplify this paradigm—Robert H. Gifford, Lloyd H. Smith, Jr., Frank Gardner, and William Castle. Finally, we would like to thank the Goldman family—Jill, Jeff, Abigail, Mira, Daniel, and Robyn Goldman—and the Schafer family—Pauline, Eric, Pam, John, Evan, and Kate—for their understanding of the time and focus required to edit a book that attempts to sustain the tradition of our predecessors and to meet the needs of today's physician.

ANDREW I. SCHAFER, MD

CONTRIBUTORS

Charles S. Abrams, MD
Professor of Medicine, Associate Chief, Hematology-Oncology, Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Thrombocytopenia

Frank J. Accurso, MD
Professor of Pediatrics, University of Colorado Denver School of Medicine, Denver, Colorado
Cystic Fibrosis

Nezam H. Afdhal, MD
Associate Professor of Medicine, Harvard Medical School; Chief of Hepatology, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Diseases of the Gallbladder and Bile Ducts

Cem Akin, MD, PhD
Lecturer, Harvard Medical School; Department of Internal Medicine, Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Boston, Massachusetts
Mastocytosis

Allen J. Aksamit, Jr., MD
Professor, Department of Neurology, Mayo Medical School; Consultant, Department of Neurology, Mayo Clinic, Rochester, Minnesota
Acute Viral Encephalitis; Poliomyelitis

Qais Al-Awqati, MB ChB
Robert F. Loeb Professor, Department of Medicine and Department of Physiology and Cellular Biophysics, Columbia University College of Physicians and Surgeons, New York, New York
Structure and Function of the Kidneys

Ban Mishu Allos, MD
Assistant Professor of Medicine and Preventive Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Campylobacter *Infections*

David Altshuler, MD, PhD
Professor of Genetics and Medicine, Harvard Medical School; Department of Molecular Biology and Medicine, Massachusetts General Hospital, Boston, Massachusetts; Deputy Director and Chief Academic Officer, Broad Institute of MIT and Harvard, Cambridge, Massachusetts
The Inherited Basis of Common Diseases

Michael J. Aminoff, MD, DSc
Professor, Department of Neurology, University of California, San Francisco, School of Medicine, San Francisco, California
Approach to the Patient with Neurologic Disease

Jeffrey L. Anderson, MD, MACP
Professor, Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City; Associate Chief of Cardiology, Intermountain Medical Center, Murray, Utah
ST Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction

Karl E. Anderson, MD
Professor of Preventive Medicine and Community Health and Internal Medicine, University of Texas Medical Branch, Galveston, Texas
The Porphyrias

Larry J. Anderson, MD
Professor and Co-Director, Division of Pediatric Infectious Diseases, Emory University School of Medicine, Atlanta, Georgia
Coronaviruses

Karen H. Antman, MD
Provost, Boston University Medical Campus, and Dean, Boston University School of Medicine, Boston, Massachusetts
Primary and Metastatic Malignant Bone Lesions

Aśok C. Antony, MD
Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Megaloblastic Anemias

Gerald B. Appel, MD
Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons; Director of Clinical Nephrology, Department of Medicine, Columbia University Medical Center, New York, New York
Glomerular Disorders and Nephrotic Syndromes

Frederick R. Appelbaum, MD
Professor and Head, Division of Oncology, University of Washington School of Medicine; Director, Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, Washington
The Acute Leukemias

William P. Arend, MD
Arend Endowed Chair in Rheumatogy and Distinguished Professor Emeritus, University of Colorado School of Medicine, Aurora, Colorado
Approach to the Patient with Rheumatic Disease

Paul Arguin, MD
Chief, Domestic Malaria Unit, Division of Parasitic Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Approach to the Patient before and after Travel

James O. Armitage, MD
The Joe Shapiro Professor of Medicine, University of Nebraska College of Medicine, Section of Oncology and Hematology, University of Nebraska Medical Center, Omaha, Nebraska
Venomous Snake Bites; Approach to the Patient with Lymphadenopathy and Splenomegaly; Non-Hodgkin's Lymphomas

Cheryl A. Armstrong, MD
Professor and Chair, Department of Dermatology, University of Arkansas for Medical Sciences; Section Chief, Dermatology Section, Central Arkansas Veterans Healthcare System, Little Rock, Arkansas
Examination of the Skin and an Approach to Diagnosing Skin Diseases

M. Amin Arnaout, MD
Professor of Medicine, Harvard Medical School; Physician and Chief, Division of Nephrology, Department of Medicine, Massachusetts General Hospital, Boston, Massachusetts
Cystic Kidney Diseases

Robert Arnold, MD
Leo H. Criep Chair in Patient Care, Department of Medicine, Section of Palliative Care and Medical Ethics, University of Pittsburgh, Pittsburgh, Pennsylvania
Care of Dying Patients and Their Families

Inherited and Metabolic Disorders of the Liver; Iron Overload (Hemochromatosis)

Grover C. Bagby, MD
Professor, Department of Medicine, Department of Molecular and Medical Genetics, Oregon Health & Science University; Staff Physician, Hematology/Oncology, Portland Veterans Affairs Medical Center, Portland, Oregon
Aplastic Anemia and Related Bone Marrow Failure States

Barbara J. Bain, MB ChB
Professor in Diagnostic Haematology, Imperial College London; Consultant Haematologist, St Mary's Hospital, London, England
The Peripheral Blood Smear

Dean F. Bajorin, MD
Professor of Medicine, Department of Medicine, Weill Cornell Medical College; Attending Physician, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, New York
Tumors of the Kidney, Bladder, Ureters, and Renal Pelvis

Mark Ballow, MD
Professor of Pediatrics, Chief, Division of Allergy and Clinical Immunology, University at Buffalo School of Medicine and Biomedical Sciences, Women & Children's Hospital of Buffalo, Buffalo, New York
Primary Immunodeficiency Diseases

Robert W. Baloh, MD
Professor of Neurology and Surgery (Head and Neck), David Geffen School of Medicine at UCLA, University of California, Los Angeles, California
Neuro-Ophthalmology; Smell and Taste; Hearing and Equilibrium

Jonathan Barasch, MD, PhD
Associate Professor of Medicine, Columbia University College of Physicians & Surgeons, New York, New York
Structure and Function of the Kidneys

Richard L. Barbano, MD, PhD
Professor of Neurology, University of Rochester; Chief of Neurology and Physical Medicine and Rehabilitation, Rochester General Hospital, Rochester, New York
Mechanical and Other Lesions of the Spine, Nerve Roots, and Spinal Cord; Videos

Murray G. Baron, MD
Professor of Radiology, Emory University School of Medicine, Atlanta, Georgia
Radiology of the Heart

Elizabeth Barrett-Connor, MD
Distinguished Professor and Chief, Division of Epidemiology, Department of Family and Preventive Medicine, University of California, San Diego, School of Medicine, La Jolla, California
Menopause

Michael J. Barry, MD
Professor of Medicine, Harvard Medical School; Medical Director, John D. Stoeckle Center for Primary Care Innovation, Massachusetts General Hospital, Boston, Massachusetts
Benign Prostatic Hyperplasia and Prostatitis

Bruce A. Barshop, MD, PhD
Professor, B. L. Maas Chair in Inherited Metabolic Disease, Department of Pediatrics, University of California, San Diego, School of Medicine, La Jolla, California
Homocystinuria and Hyperhomocysteinemia

John G. Bartlett, MD
Stanhope Bayne-Jones Professor of Medicine, Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, Maryland
Bioterrorism

Mary Barton, MD, MPP
Scientific Director, U.S. Preventive Services Task Force, Center for Primary Care, Prevention and Clinical Partnerships, Agency for Healthcare Research and Quality, Rockville, Maryland
The Periodic Health Examination

Robert C. Basner, MD
Associate Professor of Clinical Medicine, Columbia University College of Physicians & Surgeons; Director, Cardiopulmonary Sleep and Ventilatory Disorders Center, Columbia University Medical Center, New York, New York
Obstructive Sleep Apnea

Stephen G. Baum, MD
Professor of Medicine and of Microbiology and Immunology, Albert Einstein College of Medicine; Senior Associate Dean for Students, Albert Einstein College of Medicine, Bronx, New York
Mycoplasma *Infections*

Daniel G. Bausch, MD, MPH&TM
Associate Professor, Department of Tropical Medicine and Section of Adult Infectious Diseases, Tulane University Health Sciences Center, New Orleans, Louisiana
Viral Hemorrhagic Fevers

Arnold S. Bayer, MD
Professor of Medicine, David Geffen School of Medicine at UCLA; Associate Chief, Adult Infectious Diseases, Senior Investigator, LA Biomedical Research Institute, Los Angeles, California
Infective Endocarditis

Hasan Bazari, MD
Associate Professor of Medicine, Harvard Medical School; Program Director, Internal Medicine Residency, Clinical Director, Nephrology Division, Massachusetts General Hospital, Boston, Massachusetts
Approach to the Patient with Renal Disease

John H. Beigel, MD
Medical Scientist, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Antiviral Therapy (Non-HIV)

George A. Beller, MD
Ruth C. Heede Professor of Cardiology, Division of Cardiovascular Medicine, Department of Medicine, University of Virginia Health System, Charlottesville, Virginia
Noninvasive Cardiac Imaging

Robert M. Bennett, MD
Professor of Medicine and Nursing, Oregon Health & Science University, Portland, Oregon
Fibromyalgia and Chronic Fatigue Syndrome

Joseph R. Berger, MD
Ruth L. Works Professor and Chairman, Department of Neurology, University of Kentucky, Lexington, Kentucky
Cytomegalovirus, Epstein-Barr Virus, and Other Slow Virus Infections of the Central Nervous System; Neurologic Complications of Human Immunodeficiency Virus Infection; Brain Abscess and Parameningeal Infections

Paul Berk, MD
Professor, Department of Medicine, Columbia University College of Physicians and Surgeons, New York, New York
Approach to the Patient with Jaundice or Abnormal Liver Tests

Nancy Berliner, MD
Professor of Medicine, Harvard Medical School; Chief, Division of Hematology, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Leukocytosis and Leukopenia

James L. Bernat, MD
Louis and Ruth Frank Professor of Neuroscience, Professor of Neurology and Medicine, Dartmouth Medical School, Hanover, New Hampshire; Attending Neurologist, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire
Coma, Vegetative State, and Brain Death

Professor, Department of Orofacial Sciences, University of California, San Francisco, School of Dentistry; Professor, Department of Pathology, University of California, San Francisco, School of Medicine, San Francisco, California
Diseases of the Mouth and Salivary Glands

Nancy Davidson, MD
Professor of Medicine and Pharmacology and Chemical Biology, University of Pittsburgh School of Medicine; Director, University of Pittsburgh Cancer Institute and UPMC Cancer Centers, Pittsburgh, Pennsylvania
Breast Cancer and Benign Breast Disorders

Lisa M. DeAngelis, MD
Professor of Neurology, Weill Cornell Medical College; Chair, Department of Neurology, Memorial Sloan-Kettering Cancer Center, New York, New York
Tumors of the Central Nervous System and Intracranial Hypertension and Hypotension

Malcolm M. DeCamp, MD
Fowler McCormick Professor of Surgery and Professor of Medicine, Northwestern University Feinberg School of Medicine; Chief, Division of Thoracic Surgery, Northwestern Memorial Hospital, Chicago, Illinois
Interventional and Surgical Approaches to Lung Disease; Video

Carlos Del Rio, MD
Hubert Professor and Chair, Hubert Department of Global Health, Rollins School of Public Health of Emory University; Professor of Medicine, Emory University School of Medicine, Atlanta, Georgia
Prevention of Human Immunodeficiency Virus Infection

George D. Demetri, MD
Associate Professor of Medicine, Harvard Medical School; Director, Ludwig Center at Dana-Farber Cancer Institute; Senior Vice President for Experimental Therapeutics, Dana-Farber Cancer Institute, Boston, Massachusetts
Sarcomas of Soft Tissue and Bone, and Other Neoplasms of Connective Tissues

Robert H. Demling, MD
Professor of Surgery, Harvard Medical School; Director of Education and Research, Department of Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Medical Aspects of Trauma and Burn Care

Patricia A. Deuster, PhD, MPH
Professor and Scientific Director, Consortium for Health and Military Performance, Department of Military and Emergency Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Rhabdomyolysis

Robert B. Diasio, MD
William J. and Charles H. Mayo Professor, Departments of Molecular Pharmacology and Experimental Therapeutics and Oncology, Mayo Medical School; Director, Mayo Clinic Cancer Center, Rochester, Minnesota
Principles of Drug Therapy

David J. Diemert, MD
Assistant Professor, Department of Microbiology, Immunology and Tropical Medicine, George Washington University; Director of Clinical Trials, Albert B. Sabin Vaccine Institute, Washington, DC
Intestinal Nematode Infections; Tissue Nematode Infections

Kathleen B. Digre, MD
Professor of Neurology and Ophthalmology, Adjunct Professor of Obstetrics and Gynecology, Director, Headache Clinic, University of Utah School of Medicine, Salt Lake City, Utah
Headaches and Other Head Pain

John M. Douglas, Jr., MD
Chief Medical Officer, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia
Papillomavirus

Jeffrey M. Drazen, MD
Distinguished Parker B. Francis Professor of Medicine, Harvard Medical School; Senior Physician, Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital; Editor-in-Chief, *New England Journal of Medicine,* Boston, Massachusetts
Asthma; Video

Stephen C. Dreskin, MD, PhD
Professor of Medicine and Immunology, Division of Allergy and Clinical Immunology, University of Colorado Denver School of Medicine, Aurora, Colorado
Urticaria and Angioedema

W. Lawrence Drew, MD, PhD
Professor, Laboratory Medicine and Medicine, University of California, San Francisco, School of Medicine, San Francisco, California
Cytomegalovirus

George L. Drusano, MD
Co-Director, Ordway Research Institute, Albany, New York
Antibacterial Chemotherapy

Thomas D. DuBose, Jr., MD
Tinsley R. Harrison Professor and Chair, Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Vascular Disorders of the Kidney; Video

F. Daniel Duffy, MD
Steven Landgarten Professor in Medical Leadership, Dean, University of Oklahoma, School of Community Medicine, Tulsa, Oklahoma
Counseling for Behavior Change

Herbert L. DuPont, MD
H. Irving Schweppe, Jr., Chair of Internal Medicine and Vice Chairman, Department of Medicine, Baylor College of Medicine; Chief, Internal Medicine, St. Luke's Episcopal Hospital; Director, Center for Infectious Diseases, University of Texas–Houston School of Public Health, Houston, Texas
Approach to the Patient with Suspected Enteric Infection

Madeleine Duvic, MD
Professor of Dermatology and Medicine, Deputy Chairman, Department of Dermatology, The University of Texas M.D. Anderson Cancer Center, Houston, Texas
Urticaria, Drug Hypersensitivity Rashes, Nodules and Tumors, and Atrophic Diseases

Kathryn M. Edwards, MD
Sarah H. Sell Professor of Pediatrics, Vanderbilt University School of Medicine, Nashville, Tennessee
Parainfluenza Viral Disease

N. Lawrence Edwards, MD
Professor of Medicine, Vice Chairman, Department of Medicine, University of Florida College of Medicine; Chief, Section of Rheumatology, Veterans Administration Medical Center, Gainesville, Florida
Crystal Deposition Diseases

Lawrence H. Einhorn, MD
Distinguished Professor of Medicine, Lance Armstrong Foundation Professor of Oncology, Indiana University School of Medicine, Indianapolis, Indiana
Testicular Cancer

Ronald J. Elin, MD, PhD
A. J. Miller Professor and Chair, Department of Pathology and Laboratory Medicine, University of Louisville School of Medicine, Louisville, Kentucky
Reference Intervals and Laboratory Values

George M. Eliopoulos, MD
Professor of Medicine, Harvard Medical School; Division of Infectious Diseases, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Principles of Anti-Infective Therapy

Perry Elliott, MBBS, MD
Reader in Inherited Cardiac Disease, The Heart Hospital, University College London, London, United Kingdom
Diseases of the Myocardium and Endocardium

Jerrold J. Ellner, MD
Professor of Medicine, Boston University; Chief, Section of Infectious Diseases, Boston Medical Center, Boston, Massachusetts
Tuberculosis

Louis J. Elsas II, MD
Professor and Chair, Department of Biochemistry and Molecular Biology, University of Miami; Professor, Department of Pediatrics, University of Miami, Miller School of Medicine, Miami, Florida
Approach to Inborn Errors of Metabolism

Dirk M. Elston, MD
Director, Department of Dermatology, Geisinger Medical Center, Danville, Pennsylvania
Arthropods and Leeches

Ezekiel J. Emanuel, MD, PhD
Chair, Department of Bioethics, The Clinical Center, National Institutes of Health, Bethesda, Maryland
Bioethics in the Practice of Medicine

Gregory F. Erickson, PhD
Professor Emeritus of Reproductive Medicine, Division of Reproductive Endocrinology, University of California, San Diego, School of Medicine, La Jolla, California
Ovaries and Development; Reproductive Endocrinology and Infertility

Armin Ernst, MD
Associate Professor of Medicine and Surgery, Harvard Medical School; Chief of Interventional Pulmonology, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Interventional and Surgical Approaches to Lung Disease

Joel D. Ernst, MD
Professor, Departments of Medicine, Pathology, and Microbiology; Director, Division of Infectious Diseases, New York University School of Medicine, New York, New York
Leprosy (Hansen's Disease)

David S. Ettinger, MD
Alex Grass Professor of Oncology, Department of Oncology, The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland
Lung Cancer and Other Pulmonary Neoplasms

Amelia Evoli, MD
Associate Professor, Department of Neuroscience, Catholic University, Rome, Italy
Disorders of Neuromuscular Transmission

Douglas O. Faigel, MD
Professor of Medicine, Mayo Medical School; Division of Gastroenterology and Hepatology, Mayo Clinic, Scottsdale, Arizona
Neoplasms of the Large and Small Intestine; Videos

Gary W. Falk, MD, MSc
Professor of Medicine, Division of Gastroenterology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Diseases of the Esophagus

Murray J. Favus, MD
Professor of Medicine, Section of Endocrinology, Diabetes and Metabolism, University of Chicago Pritzker School of Medicine, Chicago, Illinois
Mineral and Bone Homeostasis

Gene Feder, MD
Professor of Primary Health Care, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom
Intimate Partner Violence

Stephan D. Fihn, MD, MPH
Professor, Medicine and Health Services, University of Washington School of Medicine; Director, Analytics and Business Intelligence, Department of Veterans Affairs, Seattle, Washington
Measuring Health and Health Care

Gary S. Firestein, MD
Professor of Medicine, Dean and Associate Vice Chancellor of Translational Medicine, University of California, San Diego, School of Medicine, La Jolla, California
Mechanisms of Inflammation and Tissue Repair

Neil Fishman, MD
Associate Professor of Medicine, University of Pennsylvania School of Medicine; Director, Department of Healthcare Epidemiology, Infection Prevention and Control; Director, Antimicrobial Stewardship Program, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Prevention and Control of Health Care–Associated Infections

Lee A. Fleisher, MD
Robert D. Dripps Professor and Chair of Anesthesiology, Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Overview of Anesthesia

Marsha D. Ford, MD
Adjunct Professor, Department of Emergency Medicine, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina; Director, Carolinas Poison Center, Carolinas Medical Center, Charlotte, North Carolina
Acute Poisoning

Chris E. Forsmark, MD
Professor of Medicine, Chief, Division of Gastroenterology, Hepatology, and Nutrition, University of Florida College of Medicine, Gainesville, Florida
Pancreatitis

Vance G. Fowler, Jr., MD, MHS
Associate Professor, Department of Medicine, Division of Infectious Diseases, Duke University Medical Center, Durham, North Carolina
Infective Endocarditis

Jay W. Fox, PhD
Professor, Department of Microbiology, University of Virginia School of Medicine, Charlottesville, Virginia
Venoms and Poisons from Marine Organisms

Manuel A. Franco, MD, PhD
Director of Postgraduate Programs, School of Sciences, Pontificia Universidad Javeriana, Bogota, Colombia
Rotaviruses, Noroviruses, and Other Gastrointestinal Viruses

Martyn A. French, MD, MB ChB
Winthrop Professor in Clinical Immunology, School of Pathology and Laboratory Medicine, University of Western Australia; Consultant Clinical Immunologist, Royal Perth Hospital, Perth, Western Australia, Australia
Immune Reconstitution Inflammatory Syndrome in HIV/AIDS

Karen Freund, MD, MPH
Professor of Medicine, Director, Women's Health Interdisciplinary Research Center, Boston University School of Medicine; Professor of Epidemiology, Boston University School of Public Health, Boston, Massachusetts
Approach to Women's Health

Linda P. Fried, MD, MPH
Dean and DeLamar Professor of Public Health and of Medicine, Senior Vice President, Columbia University Medical Center; Professor of Epidemiology, Columbia University Mailman School of Public Health, New York, New York
Epidemiology of Aging: Implications of the Aging of Society

Cem Gabay, MD
Professor of Medicine, University of Geneva School of Medicine; Head, Division of Rheumatology, University Hospitals of Geneva, Geneva, Switzerland
Biologic Agents

Kenneth L. Gage, PhD
Chief, Flea-Borne Diseases Activity, Division of Vector-Borne Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado
Plague and Other Yersinia *Infections*

Robert F. Gagel, MD
Head, Division of Internal Medicine, Endocrine Neoplasia and Hormonal Disorders, The University of Texas M.D. Anderson Cancer Center, Houston, Texas
Endocrine Manifestations of Tumors: "Ectopic" Hormone Production

John N. Galgiani, MD
Professor of Medicine and Director, Valley Fever Center for Excellence, University of Arizona; Chief Medical Officer, Valley Fever Solutions Inc., Tucson, Arizona
Coccidioidomycosis

Patrick G. Gallagher, MD
Professor, Department of Pediatrics and Genetics, Yale University School of Medicine, New Haven, Connecticut
Hemolytic Anemias: Red Cell Membrane and Metabolic Defects

Eithan Galun, MD
Professor, Director, Goldyne Savad Institute of Gene Therapy, Hadassah Hebrew University Hospital, Jerusalem, Israel
Gene and Cell Therapy

Leonard Ganz, MD
Associate Professor of Medicine, University of Pittsburgh School of Medicine, UPMC-Shadyside, Pittsburgh, Pennsylvania
Electrocardiography

Guadalupe Garcia-Tsao, MD
Professor of Medicine, Section of Digestive Diseases, Yale University School of Medicine, New Haven, Connecticut; Chief, Digestive Diseases, VA-CT Healthcare System, West Haven, Connecticut
Cirrhosis and Its Sequelae

Jonathan D. Gates, MD, MBA
Assistant Professor of Surgery, Harvard Medical School; Director, Trauma Center and Vascular Surgeon, Brigham and Women's Hospital, Boston, Massachusetts
Medical Aspects of Trauma and Burn Care

William M. Geisler, MD, MPH
Associate Professor of Medicine and Epidemiology, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama
Diseases Caused by Chlamydiae

Tony P. George, MD
Professor, Department of Psychiatry, Psychology and Medical Sciences, University of Toronto, Toronto, Ontario, Canada
Nicotine and Tobacco

Dale N. Gerding, MD
Professor, Department of Medicine, Loyola University Chicago Stritch School of Medicine, Maywood; Associate Chief of Staff for Research, Research Service, Hines Veterans Affairs Hospital, Hines, Illinois
Clostridial Infections

M. Eric Gershwin, MD
Distinguished Professor of Medicine, Chief, Division of Rheumatology, Allergy and Clinical Immunology, University of California, Davis, School of Medicine, Davis, California
Sjögren's Syndrome

Morie A. Gertz, MD
Professor and Chair, Department of Medicine, Mayo Medical School and Mayo Clinic, Rochester, Minnesota
Amyloidosis

Gordon D. Ginder, MD
Professor, Internal Medicine, Virginia Commonwealth University; Director, Massey Cancer Center, Virginia Commonwealth University, Richmond, Virginia
Microcytic and Hypochromic Anemias

Jeffrey Ginsberg, MD
Professor, Department of Medicine, McMaster University, Hamilton, Ontario, Canada
Peripheral Venous Disease

Geoffrey S. Ginsburg, MD, PhD
Professor of Medicine and Pathology, Duke University School of Medicine; Director, Center for Genomic Medicine, Institute for Genome Sciences and Policy; Director, Center for Personalized Medicine, Durham, North Carolina
Applications of Molecular Technologies to Clinical Medicine

Michael Glogauer, DDS, PhD
Associate Professor, Faculty of Dentistry, University of Toronto, Toronto, Ontario, Canada
Disorders of Phagocyte Function

John W. Gnann, Jr., MD
Professor of Medicine, Pediatrics, and Microbiology, University of Alabama at Birmingham School of Medicine and Birmingham Veterans Affairs Medical Center, Birmingham, Alabama
Mumps

Matthew R. Golden, MD, MPH
Associate Professor of Medicine, Director, PHSKC HIV/STD Program, University of Washington Center for AIDS and STD, Harborview Medical Center, Seattle, Washington
Neisseria Gonorrhoeae *Infections*

Lee Goldman, MD
Dean of the Faculties of Health Sciences and Medicine, Executive Vice President for Health and Biomedical Sciences, Harold and Margaret Hatch Professor of the University, Professor of Medicine and of Epidemiology, Columbia University, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Approach to the Patient with Possible Cardiovascular Disease

Ellie J. Goldstein, MD
Clinical Professor of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California; Director, R.M. Alden Research Laboratory, Santa Monica, California
Diseases Caused by Non–Spore-Forming Anaerobic Bacteria

Lawrence T. Goodnough, MD
Professor of Pathology and Medicine, Stanford University School of Medicine; Director, Transfusion Service, Stanford University Medical Center, Stanford, California
Transfusion Medicine

Jörg J. Goronzy, MD, PhD
Professor of Medicine, Division of Immunology and Rheumatology, Stanford University School of Medicine, Stanford, California
The Innate and Adaptive Immune Systems

Eduardo Gotuzzo, MD
Principal Professor of Medicine, Universidad Peruana Cayetano Heredia; Director, Instituto de Medicina Tropical "Alexander von Humboldt," Lima, Peru
Cholera and Other Vibrio *Infections; Liver, Intestinal, and Lung Fluke Infections*

Deborah Grady, MD, MPH
Professor, Department of Medicine, University of California, San Francisco, School of Medicine; Associate Dean for Clinical and Translational Research, University of California, San Francisco, San Francisco, California
Menopause

Leslie C. Grammer, MD
Professor, Department of Medicine, Division of Allergy-Immunology, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Drug Allergy

F. Anthony Greco, MD
Medical Director, Sarah Cannon Cancer Center, Nashville, Tennessee
Cancer of Unknown Primary Origin

Harry B. Greenberg, MD
Joseph D. Grant Professor of Medicine and Microbiology and Immunology; Senior Associate Dean of Research; Stanford University School of Medicine, Stanford, California
Rotaviruses, Noroviruses, and Other Gastrointestinal Viruses

Peter K. Gregersen, MD
Professor, Molecular Medicine, Director, Robert S. Boas Center for Genomics and Human Genetics, The Feinstein Institute for Medical Research, Hofstra University School of Medicine, Manhasset, New York
The Major Histocompatibility Complex

Robert C. Griggs, MD
Professor of Neurology, Medicine, Pediatrics, and Pathology and Laboratory Medicine, University of Rochester School of Medicine and Dentistry, Rochester, New York
Approach to the Patient with Neurologic Disease

Lisa M. Guay-Woodford, MD
Professor and Vice Chair, Department of Genetics; Pediatric Nephrologist, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama
Hereditary Nephropathies and Developmental Abnormalities of the Urinary Tract

Richard L. Guerrant, MD
Thomas H. Hunter Professor of International Medicine, Infectious Diseases, and International Health, Director, Center for Global Health, University of Virginia School of Medicine, Charlottesville, Virginia
Escherichia Coli *Enteric Infections; Cryptosporidiosis*

Colleen Hadigan, MD, MPH
Staff Clinician, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Treatment of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

John D. Hainsworth, MD
Chief Scientific Officer, Sarah Cannon Research Institute, Nashville, Tennessee
Cancer of Unknown Primary Origin

Anders Hamsten, MD, PhD
Professor of Cardiovascular Diseases, Department of Medicine, Center for Molecular Medicine, Karolinska University Hospital, Karolinska Institutet, Stockholm, Sweden
Atherosclerosis, Thrombosis, and Vascular Biology

Kenneth R. Hande, MD
Professor, Departments of Medicine and Pharmacology, Vanderbilt University School of Medicine, Nashville, Tennessee
Carcinoid Syndrome

H. Hunter Handsfield, MD
Clinical Professor of Medicine, Center for AIDS and STD, University of Washington School of Medicine; Senior Research Leader, Battelle Centers for Public Health Research and Evaluation, Seattle, Washington
Neisseria Gonorrhoeae *Infections*

Göran K. Hansson, MD, PhD
Professor, Center for Molecular Medicine, Department of Medicine, Karolinska University Hospital, Karolinska Institutet, Stockholm, Sweden
Atherosclerosis, Thrombosis, and Vascular Biology

Rashidul Haque, MB, PhD
Senior Scientist and Head, Parasitology Laboratory, Laboratory Sciences Division, International Centre for Diarrheal Disease Research, Bangladesh (ICDDR,B), Dhaka, Bangladesh
Amebiasis

Raymond C. Harris, MD
Anne and Roscoe R. Robinson Professor of Medicine and Chief, Division of Nephrology, Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Diabetes and the Kidney

Stephen Crane Hauser, MD
Associate Professor of Medicine, Mayo Medical School; Consultant, Division of Internal Medicine, Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota
Vascular Diseases of the Gastrointestinal Tract

Frederick G. Hayden, MD
Richardson Professor of Clinical Virology, Professor of Medicine, University of Virginia School of Medicine, Charlottesville, Virginia
Influenza

Letha Healey, MD
Staff Clinician, Critical Care Medicine Department, Clinical Center, National Institutes of Health, Bethesda, Maryland
Treatment of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Douglas C. Heimburger, MD, MS
Professor of Medicine, Associate Director for Education and Training, Vanderbilt Institute for Global Health, Vanderbilt University School of Medicine, Nashville, Tennessee
Nutrition's Interface with Health and Disease

Erik L. Hewlett, MD
Professor of Medicine and Pharmacology, Division of Infectious Diseases and International Health, University of Virginia School of Medicine, Charlottesville, Virginia
Whooping Cough and Other Bordetella *Infections*

David R. Hill, MD, DTM&H
Director, National Travel Health Network and Centre; Honorary Professor, London School of Hygiene and Tropical Medicine, London, England
Giardiasis

Nicholas S. Hill, MD
Professor of Medicine, Tufts University School of Medicine; Chief, Division of Pulmonary, Critical Care, and Sleep Medicine, Tufts Medical Center, Boston, Massachusetts
Respiratory Monitoring in Critical Care

L. David Hillis, MD
Professor and Chair, Department of Medicine, University of Texas Health Science Center at San Antonio, San Antonio, Texas
Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction

Jack Hirsh, MD, DSc
Professor Emeritus, McMaster University, Hamilton, Ontario, Canada
Antithrombotic Therapy

V. Michael Holers, MD
Scoville Professor of Rheumatology, Department of Medicine, University of Colorado Denver School of Medicine, Aurora, Colorado
Complement in Health and Disease

Steven M. Holland, MD
Chief, Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
The Nontuberculous Mycobacteria

Steven Hollenberg, MD
Professor of Medicine, Robert Wood Johnson Medical School/UMDNJ; Director, Coronary Care Unit, Cooper University Hospital, Camden, New Jersey
Cardiogenic Shock

Edward W. Hook III, MD
Professor of Medicine, Epidemiology, and Microbiology, Director, Division of Infectious Diseases, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama
Granuloma Inguinale (Donovanosis); Syphilis; Nonsyphilitic Treponematoses

Laurence Huang, MD
Professor of Medicine, University of California, San Francisco, School of Medicine; Chief, HIV/AIDS Chest Clinic, San Francisco General Hospital, San Francisco, California
Pulmonary Manifestations of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Leonard D. Hudson, MD
Professor of Medicine, Endowed Chair in Pulmonary Disease Research, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Seattle, Washington
Acute Respiratory Failure; Mechanical Ventilation

Steven E. Hyman, MD
Provost, Harvard University, Cambridge, Massachusetts; Professor, Department of Neurobiology, Harvard Medical School, Boston, Massachusetts
Biology of Addiction

Michael Iannuzzi, MD, MBA
Edward C. Reifenstein Professor and Chair, Department of Medicine, Upstate Medical University, Syracuse, New York
Sarcoidosis

Robert D. Inman, MD
Professor of Medicine and Immunology, University of Toronto; Director, Arthritis Center of Excellence, Toronto Western Hospital, Toronto, Ontario, Canada
The Spondyloarthropathies

Sharon K. Inouye, MD, MPH
Professor of Medicine, Harvard Medical School; Director, Aging Brain Center, Milton and Shirley F. Levy Family Chair, Institute for Aging Research, Hebrew SeniorLife; Faculty, Division of Gerontology, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Neuropsychiatric Aspects of Aging; Delirium or Acute Mental Status Change in the Older Patient; Video

Karl L. Insogna, MD
Professor of Medicine, Section of Endocrinology, Department of Internal Medicine, Director, Yale Bone Center, Yale University School of Medicine, New Haven, Connecticut
The Parathyroid Glands, Hypercalcemia, and Hypocalcemia

Silvio E. Inzucchi, MD
Professor of Medicine, Clinical Director, Section of Endocrinology, Yale University School of Medicine; Director, Yale Diabetes Center, Yale-New Haven Hospital, New Haven, Connecticut
Type 1 Diabetes Mellitus; Type 2 Diabetes Mellitus

Eric M. Isselbacher, MD
Associate Professor of Medicine, Harvard Medical School; Associate Director, Heart Center and Co-Director, Thoracic Aortic Center, Massachusetts General Hospital, Boston, Massachusetts
Diseases of the Aorta

Ahmedin Jemal, DVM, PhD
Vice President, Surveillance Research, American Cancer Society, Inc., Atlanta, Georgia
The Epidemiology of Cancer

Joanna Jen, MD, PhD
Professor, Department of Neurology, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California
Neuro-Ophthalmology; Smell and Taste; Hearing and Equilibrium

Dennis M. Jensen, MD
Professor of Medicine, David Geffen School of Medicine at UCLA, University of California, Los Angeles, CURE Digestive Diseases Research Center; Staff Physician, West Los Angeles Veterans Affairs Medical Center, Los Angeles, California
Gastrointestinal Hemorrhage and Occult Gastrointestinal Bleeding

Michael D. Jensen, MD
Professor of Medicine, Department of Endocrinology, Mayo Clinic, Rochester, Minnesota
Obesity

Robert T. Jensen, MD
Chief, Cell Biology Section, Digestive Diseases Branch, National Institute of Diabetes, Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland
Pancreatic Endocrine Tumors

Mariell Jessup, MD
Professor of Medicine, Department of Medicine, University of Pennsylvania School of Medicine; Medical Director, Penn Heart and Vascular Center, University of Pennsylvania Health System; Associate Chief, Clinical Affairs, Cardiovascular Division, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Cardiac Transplantation

Stuart Johnson, MD
Professor of Medicine, Loyola University Chicago Stritch School of Medicine, Maywood; Deputy Associate Chief of Staff for Research, Hines Veterans Affairs Hospital, Hines, Illinois
Clostridial Infections

Ralph F. Józefowicz, MD
Professor of Neurology and Medicine, Associate Chair for Education, Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, New York
Approach to the Patient with Neurologic Disease

Stephen G. Kaler, MD
Molecular Medicine Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, Maryland
Wilson's Disease

Moses R. Kamya, MD, PhD
Professor of Medicine, Chair, Department of Medicine, School of Medicine, Makerere University College of Health Sciences, Kampala, Uganda
Malaria

Hagop Kantarjian, MD
Professor and Kelcie Margaret Kana Research Chair, Department of Leukemia, The University of Texas M. D. Anderson Cancer Center, Houston, Texas
The Chronic Leukemias

David R. Karp, MD, PhD
Professor and Chief, Rheumatic Diseases Division, The University of Texas Southwestern Medical Center at Dallas, Dallas, Texas
Complement in Health and Disease

Daniel L. Kastner, MD, PhD
NIH Distinguished Investigator, Scientific Director, Division of Intramural Research, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland
The Systemic Autoinflammatory Diseases

David A. Katzka, MD
Professor of Medicine, Mayo Medical School, Rochester, Minnesota
Diseases of the Esophagus

Debra K. Katzman, MD
Professor of Pediatrics, Department of Pediatrics, University of Toronto; Head, Division of Adolescent Medicine, Senior Associate Scientist, Research Institute, The Hospital for Sick Children and University of Toronto, Toronto, Ontario, Canada
Adolescent Medicine

Carol A. Kauffman, MD
Professor, University of Michigan; Chief, Infectious Diseases Section, Veterans Affairs Ann Arbor Healthcare System, Ann Arbor, Michigan
Histoplasmosis; Blastomycosis; Paracoccidioidomycosis; Cryptococcosis; Sporotrichosis; Candidiasis

Kenneth Kaushansky, MD, MACP
Senior Vice President, Health Sciences, Dean, School of Medicine, Stony Brook University, Health Sciences Center, Stony Brook, New York
Hematopoiesis and Hematopoietic Growth Factors

Emmet B. Keeffe, MD
Professor of Medicine Emeritus, Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University Medical Center, Stanford, California
Hepatic Failure and Liver Transplantation

Morton Kern, MD
Professor of Medicine, Associate Chief, Cardiology, University of California Irvine, Orange; Chief, Cardiology, Long Beach Veterans Administration Hospital, Long Beach, California
Catheterization and Angiography

Gerald T. Keusch, MD
Professor, International Health, Boston University School of Public Health; Associate Director, National Emerging Infectious Diseases Laboratory, Boston University, Boston, Massachusetts
Shigellosis

David H. Kim, MD
Associate Professor of Radiology, Section of Abdominal Imaging, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
Diagnostic Imaging Procedures in Gastroenterology

Matthew Kim, MD
Instructor in Medicine, Harvard Medical School; Associate Physician, Division of Endocrinology, Diabetes and Hypertension, Brigham and Women's Hospital, Boston, Massachusetts
Thyroid

Louis V. Kirchhoff, MD, MPH
Professor, Departments of Internal Medicine (Infectious Diseases) and Epidemiology, University of Iowa; Staff Physician, Medical Service, Department of Veterans Affairs Medical Center, Iowa City, Iowa
Chagas' Disease

Michael J. Klag, MD, MPH
Dean, The Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland
Epidemiology of Cardiovascular Disease

Samuel Klein, MD
William H. Danforth Professor of Medicine and Nutritional Science, Director, Center for Human Nutrition, Washington University School of Medicine, St. Louis, Missouri
Protein-Energy Malnutrition

David S. Knopman, MD
Professor of Neurology and Consultant in Neurology, Mayo Clinic, Rochester, Minnesota
Regional Cerebral Dysfunction: Higher Mental Functions; Alzheimer's Disease and Other Dementias

Tamsin A. Knox, MD, MPH
Associate Professor of Medicine, Nutrition/Infection Unit, Tufts University School of Medicine, Boston, Massachusetts
Gastrointestinal Manifestions of HIV and AIDS

Albert I. Ko, MD
Associate Professor of Epidemiology and Medicine, Division Head, Epidemiology of Microbial Disease, Yale School of Public Health, New Haven, Connecticut; Collaborating Researcher, Oswaldo Cruz Foundation, Brazilian Ministry of Health, Salvador, Brazil
Leptospirosis

Rami S. Komrokji, MD
Associate Professor, Department of Oncologic Sciences, University of South Florida; Clinical Director, Department of Malignant Hematology, Associate Member, Moffitt Cancer Center and Research Institute, Tampa, Florida
Myelodysplastic Syndrome

Dimitrios P. Kontoyiannis, MD, ScD
Professor of Medicine and Deputy Chair, The University of Texas M.D. Anderson Cancer Center, Houston, Texas
Mucormycosis; Mycetoma

Barbara S. Koppel, MD
Professor of Clinical Neurology, New York Medical College, Valhalla, New York; Chief of Service, Metropolitan Hospital, New York, New York
Nutritional and Alcohol-Related Neurologic Disorders

Kevin Korenblat, MD
Associate Professor of Medicine, Washington University School of Medicine, St. Louis, Missouri
Approach to the Patient with Jaundice or Abnormal Liver Tests

Bruce R. Korf, MD, PhD
Professor and Wayne H. and Sara Crews Finley Chair in Medical Genetics, Department of Genetics; Director, Heflin Center for Genomic Sciences, University of Alabama at Birmingham, Birmingham, Alabama
Principles of Genetics

Neil J. Korman, MD, PhD
Professor, Department of Dermatology, Case Western Reserve University; Clinical Director, Murdough Family Center for Psoriasis, University Hospitals Case Medical Center, Cleveland, Ohio
Macular, Papular, Vesiculobullous, and Pustular Diseases

Joseph A. Kovacs, MD
Senior Investigator, Critical Care Medicine Department, National Institutes of Health, Bethesda, Maryland
Pneumocystis *Pneumonia*

Monica Kraft, MD
Professor of Medicine, Vice Chair for Research, Department of Medicine; Director, Duke Asthma, Allergy and Airway Center, Duke University Medical Center, Durham, North Carolina
Approach to the Patient with Respiratory Disease

Christopher M. Kramer, MD
Professor of Radiology and Medicine, Director, Cardiovascular Imaging Center, University of Virginia Health System, Charlottesville, Virginia
Noninvasive Cardiac Imaging

Donna M. Krasnewich, MD, PhD
Program Director, National Institute of General Medical Sciences, National Institutes of Health, Bethesda, Maryland
The Lysosomal Storage Diseases

Peter J. Krause, MD
Senior Research Scientist, Yale School of Public Health, Yale School of Medicine, New Haven, Connecticut
Babesiosis and Other Protozoan Diseases

Henry M. Kronenberg, MD
Professor of Medicine, Harvard Medical School; Chief, Endocrine Unit, Massachusetts General Hospital, Boston, Massachusetts
Polyglandular Disorders

Ernst J. Kuipers, MD, PhD
Professor of Medicine, Department of Gastroenterology and Hepatology, Department of Internal Medicine, Erasmus MC University Medical Center, Rotterdam, The Netherlands
Acid Peptic Disease

Paul Ladenson, MD
John Eager Howard Professor of Endocrinology; Professor of Medicine, Pathology, Oncology, Radiology and Radiological Sciences; Distinguished Service Professor, and Director, Division of Endocrinology and Metabolism, Johns Hopkins University School of Medicine, Baltimore, Maryland
Thyroid

Donald W. Landry, MD, PhD
Samuel Bard Professor of Medicine and Chair, Department of Medicine, Columbia University College of Physicians and Surgeons, New York, New York
Approach to the Patient with Renal Disease

Nancy E. Lane, MD
Professor of Medicine and Rheumatology, University of California, Davis, School of Medicine; Director, Aging Center, University of California at Davis Medical Center, Davis, California
Osteoarthritis

Anthony E. Lang, MD
Professor, Department of Medicine (Neurology), University of Toronto; Director, Movement Disorders Center, Toronto Western Hospital; Director, Division of Neurology, Jack Clark Chair for Parkinson's Disease Research, Toronto, Ontario, Canada
Parkinsonism; Other Movement Disorders; Videos

Richard A. Lange, MD, MBA
Professor and Executive Vice Chairman, Department of Medicine, University of Texas Health Science Center San Antonio, San Antonio, Texas
Acute Coronary Syndrome: Unstable Angina and Non-ST Elevation Myocardial Infarction

George V. Lawry, MD
Clinical Professor of Medicine, Chief, Division of Rheumatology, University of California Irvine, Orange, California
Approach to the Patient with Rheumatic Disease

Thomas H. Lee, MD, MSc
Professor of Medicine, Harvard Medical School; Network President, Partners Healthcare System, Boston, Massachusetts
Using Data for Clinical Decisions

William M. Lee, MD
Professor, Department of Internal Medicine, Division of Digestive and Liver Diseases, University of Texas Southwestern Medical Center, Dallas, Texas
Toxin- and Drug-Induced Liver Disease

James Leggett, MD
Associate Professor of Medicine, Oregon Health & Science University; Assistant Director of Medical Education, Providence Portland Medical Center, Portland, Oregon
Approach to Fever or Suspected Infection in the Normal Host

Adam Lerner, MD
Professor, Department of Medicine, Section of Hematology and Medical Oncology, Boston University School of Medicine, Boston, Massachusetts
Primary and Metastatic Malignant Bone Lesions

Stuart Levin, MD
The Ralph C. Brown, MD, Professor of Medicine and Chair, Department of Internal Medicine, Rush University Medical Center, Chicago, Illinois
Zoonoses

Stephanie M. Levine, MD
Professor of Medicine, Division of Pulmonary and Critical Care Diseases, University of Texas Health Science Center at San Antonio, San Antonio, Texas
Alveolar Filling Disorders

Gary R. Lichtenstein, MD
Professor of Medicine, Division of Gastroenterology, University of Pennsylvania School of Medicine; Director, Center for Inflammatory Bowel Diseases, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Inflammatory Bowel Disease

Henry W. Lim, MD, DSc
Chairman and C.S. Livingood Chair, Department of Dermatology, Henry Ford Hospital; Senior Vice President for Academic Affairs, Henry Ford Health System, Detroit, Michigan
Eczema, Photodermatoses, Papulosquamous (including Fungal) Diseases, and Figurate Erythemas

Aldo A. M. Lima, MD, PhD
Professor of Medicine and INCT-Biomedicine, Department of Physiology and Pharmacology, Federal University of Ceará, Fortaleza-Ceará, Brazil
Cryptosporidiosis; Schistosomiasis (Bilharziasis)

Andrew H. Limper, MD
Professor and Division Chair, Pulmonary and Critical Care Medicine, and Director, Thoracic Diseases Research Unit, Mayo Medical School; Consultant, Mayo Clinic, Rochester, Minnesota
Overview of Pneumonia

Geoffrey S. F. Ling, MD, PhD
Professor and Interim Chair, Department of Neurology, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Director of Neuro Critical Care, Critical Care Medicine, Walter Reed Army Medical Center, Washington, DC
Traumatic Brain Injury and Spinal Cord Injury

Alan F. List, MD
Professor of Oncologic Sciences, University of South Florida; Executive Vice President and Physician-in-Chief, Moffitt Cancer Center; Senior Member, Malignant Hematology, Moffitt Cancer Center, Tampa, Florida
Myelodysplastic Syndrome

William C. Little, MD
McMichael Professor and Vice Chair, Department of Internal Medicine, Chief of Cardiology, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Pericardial Diseases

Richard F. Loeser, MD
Professor of Internal Medicine, Section of Molecular Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Connective Tissue Structure and Function

Bennett Lorber, MD
Thomas M. Durant Professor of Medicine, Professor of Microbiology and Immunology, Temple University School of Medicine, Philadelphia, Pennsylvania
Listeriosis

Donald E. Low, MD
Professor, Laboratory Medicine and Pathobiology, University of Toronto; Microbiologist-in-Chief, Mount Sinai Hospital/University Health Network; Medical Director, Public Health Laboratory–Toronto, Ontario Agency for Health Protection and Promotion, Toronto, Ontario, Canada
Nonpneumococcal Streptococcal Infections, Rheumatic Fever

Daniel R. Lucey, MD, MPH
Adjunct Professor of Microbiology and Immunology, Georgetown University Medical Center; Director, Center for Biologic Counterterrorism and Emerging Diseases, Washington Hospital Center, Washington, DC
Anthrax

James R. Lupski, MD, PhD
Cullen Professor and Vice Chair of Molecular and Human Genetics, Professor of Pediatrics, Baylor College of Medicine; Attending Medical Geneticist, Texas Children's Hospital, Ben Taub General Hospital, Houston, Texas
Gene, Genomic, and Chromosomal Disorders

Henry T. Lynch, MD
Chair, Preventive Medicine and Public Health, Professor of Medicine, Director, Creighton Hereditary Cancer Institute, Creighton University School of Medicine, Omaha, Nebraska
Cancer Genetics

Jeffrey M. Lyness, MD
Professor and Associate Chair for Education, Department of Psychiatry, University of Rochester School of Medicine and Dentistry; Medical Director for Continuing Medical Education, University of Rochester Medical Center, Rochester, New York
Psychiatric Disorders in Medical Practice

Bruce W. Lytle, MD
Chair, Heart and Vascular Institute, Department of Thoracic and Cardiovascular Surgery, The Cleveland Clinic, Cleveland, Ohio
Interventional and Surgical Treatment of Coronary Artery Disease

C. Ronald MacKenzie, MD
Associate Professor of Clinical Medicine, Department of Rheumatology, Hospital for Special Surgery and Weill Cornell Medical College, New York, New York
Surgical Treatment of Joint Disease

Harriet MacMillan, MD, MSc
Professor, Departments of Psychiatry and Behavioral Neurosciences, and Pediatrics, David R. (Dan) Offord Chair in Child Studies, Offord Centre for Child Studies, McMaster University, Hamilton, Ontario, Canada
Intimate Partner Violence

Robert D. Madoff, MD
Stanley M. Goldberg, MD, Professor of Surgery, Chief, Division of Colon and Rectal Surgery, University of Minnesota Medical School, Minneapolis, Minnesota
Diseases of the Rectum and Anus

Mark W. Mahowald, MD
Professor, Department of Neurology, University of Minnesota Medical School, Minneapolis, Minnesota
Disorders of Sleep

Atul Malhotra, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston, Massachusetts
Disorders of Ventilatory Control

Lionel A. Mandell, MD
Professor of Medicine, Faculty of Health Sciences at McMaster University; Attending Physician, Department of Medicine, Henderson Division, Hamilton Health Sciences, Hamilton, Ontario, Canada
Streptococcus pneumoniae *Infections*

Peter Manu, MD
Professor of Medicine, Hofstra North Shore–LIJ School of Medicine at Hofstra University, Hempstead; Director of Medical Services, The Zucker Hillside Hospital, Glen Oaks, New York
Medical Consultation in Psychiatry

Marsha D. Marcus, PhD
Professor of Psychiatry and Psychology, University of Pittsburgh School of Medicine; Chief, Eating Disorders Program, Western Psychiatric Institute and Clinic, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Eating Disorders

Ariane J. Marelli, MD, MPH
Associate Professor, McGill University Health Center; Director, McGill Adult Unit for Congenital Heart Disease, McGill University, Montreal, Quebec, Canada
Congenital Heart Disease in Adults; Videos

Maurie Markman, MD
Vice President for Patient Oncology Services, National Director for Medical Oncology, Cancer Treatment Centers of America, Eastern Regional Medical Center, Philadelphia, Pennsylvania
Gynecologic Cancers

Andrew R. Marks, MD
Wu Professor and Chair, Department of Physiology and Cellular Biophysics and Director, Helen and Clyde Wu Center for Molecular Cardiology, Columbia University College of Physicians and Surgeons, New York, New York
Cardiac Function and Circulatory Control

Kieren A. Marr, MD
Professor of Medicine and Oncology, Director, Transplant and Oncology Infectious Disease Program, Johns Hopkins University School of Medicine, Johns Hopkins University, Baltimore, Maryland
Approach to Fever and Suspected Infection in the Compromised Host

Thomas J. Marrie, MD
Dean, Faculty of Medicine, Dalhousie University, Halifax, Nova Scotia, Canada
Legionella *Infections*

Paul Martin, MD
Professor of Medicine, Chief, Division of Hepatology, University of Miami, Miller School of Medicine, Miami, Florida
Approach to the Patient with Liver Disease

Joel B. Mason, MD
Professor of Medicine and Nutrition, Tufts University; Staff Physician, Tufts Medical Center; Director, Vitamins and Carcinogenesis Laboratory, U.S.D.A. Human Nutrition Research Center at Tufts University, Boston, Massachusetts
Vitamins, Trace Minerals, and Other Micronutrients

Barry M. Massie, MD
Professor of Medicine, University of California, San Francisco, School of Medicine; Chief, Cardiology Division, San Francisco VA Medical Center, San Francisco, California
Heart Failure: Pathophysiology and Diagnosis

Henry Masur, MD
Chief, Critical Care Medicine Department, Clinical Center, National Institutes of Health, Bethesda, Maryland
Treatment of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Eric L. Matteson, MD, MPH
Professor of Medicine, Division of Rheumatology and Division of Epidemiology, Mayo Medical School, Rochester, Minnesota
Infections of Bursae, Joints, and Bones

Toby Maurer, MD
Professor, Department of Dermatology, University of California, San Francisco, School of Medicine, San Francisco, California
Skin Manifestations in Patients with Human Immunodeficiency Virus Infection

Emeran A. Mayer, MD
Professor of Medicine, Physiology and Psychiatry; Director, Center for Neurobiology of Stress, Division of Digestive Diseases, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California
Functional Gastrointestinal Disorders: Irritable Bowel Syndrome, Dyspepsia, and Functional Chest Pain of Presumed Esophageal Origin

Stephen A. McClave, MD
Professor of Medicine, Director of Clinical Nutrition, Division of Gastroenterology, Hepatology, and Nutrition, University of Louisville School of Medicine, Louisville, Kentucky
Enteral Nutrition

F. Dennis McCool, MD
Professor of Medicine, Alpert Medical School of Brown University, Providence, Rhode Island; Chief of Pulmonary Critical Care and Sleep Medicine, Memorial Hospital of Rhode Island, Pawtucket, Rhode Island
Diseases of the Diaphragm, Chest Wall, Pleura, and Mediastinum

Charles E. McCulloch, PhD
Professor and Head, Division of Biostatistics, Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, California
Statistical Interpretation of Data

Michael A. McGuigan, MDCM, MBA
Clinical Professor, Department of Emergency Medicine, State University of New York, Stony Brook; Medical Director, Long Island Regional Poison and Drug Information Center, Winthrop-University Hospital, Mineola, New York
Chronic Poisoning: Trace Metals and Others

John McHutchison, MD
Senior Vice President, Liver Disease Therapeutics, Gilead Sciences Inc., Foster City, California
Chronic Viral and Autoimmune Hepatitis

William McKenna, MD, DSc
Professor of Cardiology, Director, Institute of Cardiovascular Science, University College London, London, United Kingdom
Diseases of the Myocardium and Endocardium

Vallerie McLaughlin, MD
Professor of Medicine, Department of Internal Medicine, Division of Cardiovascular Medicine, and Director, Pulmonary Hypertension Program, University of Michigan, Ann Arbor, Michigan
Pulmonary Hypertension

John J. V. McMurray, MB, MD
Professor of Medical Cardiology, University of Glasgow; Honorary Consultant Cardiologist, Western Infirmary, Glasgow, Scotland, United Kingdom
Heart Failure: Management and Prognosis

Mary McNaughton-Collins, MD, MPH
Associate Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Benign Prostatic Hyperplasia and Prostatitis

Kenneth McQuaid, MD
Professor of Clinical Medicine, University of California, San Francisco, School of Medicine; Chief, Gastroenterology Section, Veterans Affairs Medical Center, San Francisco, California
Approach to the Patient with Gastrointestinal Disease

Frederick W. Miller, MD, PhD
Chief, Environmental Autoimmunity Group, National Institute of Environmental Health Sciences, National Institutes of Health, Bethesda, Maryland
Polymyositis and Dermatomyositis

Kenneth L. Minaker, MD
Associate Professor of Medicine, Harvard Medical School; Chief, Geriatric Medicine Unit, Interim Chief, General Medicine Division, Massachusetts General Hospital, Boston, Massachusetts
Common Clinical Sequelae of Aging

Jonathan W. Mink, MD, PhD
Professor and Chief of Child Neurology, Departments of Neurology, Pediatrics, Brain and Cognitive Sciences, and Neurobiology and Anatomy, University of Rochester, Rochester, New York
Congenital, Developmental, and Neurocutaneous Disorders

Daniel R. Mishell, Jr., MD
Professor, Department of Obstetrics and Gynecology, University of Southern California, Keck School of Medicine, Los Angeles, California
Contraception

William E. Mitch, MD
Gordon Cain Chair in Nephrology and Director, Division of Nephrology, Department of Medicine, Baylor College of Medicine, Houston, Texas
Chronic Kidney Disease

Mark E. Molitch, MD
Professor of Medicine, Northwestern University Feinberg School of Medicine; Attending Physician, Northwestern Memorial Hospital, Chicago, Illinois
Neuroendocrinology and the Neuroendocrine System; Anterior Pituitary

Bruce A. Molitoris, MD
Professor of Medicine, Director of Nephrology, Director of the Indiana Center for Biological Microscopy, Indiana University School of Medicine, Indianapolis, Indiana
Acute Kidney Injury

José G. Montoya, MD
Associate Professor, Department of Medicine, Stanford University School of Medicine, Stanford, California; Director, Toxoplasma Serology Laboratory, Palo Alto Medical Foundation, Palo Alto, California
Toxoplasmosis

Fred Morady, MD
McKay Professor of Cardiovascular Diseases, Professor of Medicine, University of Michigan Health System, Ann Arbor, Michigan
Electrophysiologic Interventional Procedures and Surgery

Jeffrey A. Moscow, MD
Children's Miracle Network Professor, Chief, Hematology-Oncology, Department of Pediatrics, University of Kentucky, Lexington, Kentucky
Biology of Cancer

Andrew H. Murr, MD
Professor of Clinical Otolaryngology and Head and Neck Surgery, Roger Boles, MD, Endowed Chair in Otolaryngology Education and Vice Chair for Clinical Affairs, Department of Otolaryngology, University of California, San Francisco, School of Medicine; Chief of Service, San Francisco General Hospital, San Francisco, California
Approach to the Patient with Nose, Sinus, and Ear Disorders

Robert J. Myerburg, MD
Professor of Medicine and Physiology, Division of Cardiovascular Medicine, American Heart Association Chair in Cardiovascular Research, University of Miami, Miller School of Medicine, Miami, Florida
Approach to Cardiac Arrest and Life-Threatening Arrhythmias

Stanley Naguwa, MD
Clinical Professor, Division of Rheumatology, Allergy, Clinical Immunology, University of California, Davis, Davis, California
Sjögren's Syndrome

Stanley J. Naides, MD
Medical Director, Department of Immunology, Quest Diagnostics Nichols Institute, San Juan Capistrano, California
Arboviruses Causing Fever and Rash Syndromes

Theodore E. Nash, MD
Head, Gastrointestinal Parasites Section, Laboratory of Parasitic Diseases, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Giardiasis

Avindra Nath, MD
Chief, Section of Infections of the Nervous System, National Institute of Neurological Diseases and Stroke, National Institutes of Health, Bethesda, Maryland
Cytomegalovirus, Epstein-Barr Virus, and Other Slow Virus Infections of the Central Nervous System; Neurologic Complications of Human Immunodeficiency Virus Infection; Meningitis: Bacterial, Viral, and Other; Brain Abscess and Parameningeal Infections

Eric G. Neilson, MD
Thomas Fearn Frist, Sr., Professor of Medicine and Cell Biology, Vanderbilt University School of Medicine, Vanderbilt University, Nashville, Tennessee
Tubulointerstitial Diseases

Lawrence S. Neinstein, MD
Professor of Pediatrics and Medicine, Keck School of Medicine; Executive Director, University Park Health Center, Chief, Division of College Health, Senior Associate Dean of Student Affairs, University of Southern California, Los Angeles, California
Adolescent Medicine

Thomas B. Newman, MD, MPH
Professor and Head, Division of Clinical Epidemiology, Departments of Epidemiology and Biostatistics and Pediatrics, University of California, San Francisco, School of Medicine, San Francisco, California
Statistical Interpretation of Data

William L. Nichols, MD
Associate Professor of Medicine and Laboratory Medicine, Hematology and Internal Medicine, Hematopathology and Laboratory Medicine, Mayo Medical School, Rochester, Minnesota
Von Willebrand Disease and Hemorrhagic Abnormalities of Platelet and Vascular Function

Lynnette K. Nieman, MD
Senior Investigator, Program on Reproductive and Adult Endocrinology, The Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), National Institutes of Health, Bethesda, Maryland
Adrenal Cortex

Dennis E. Niewoehner, MD
Professor, Department of Medicine, University of Minnesota Medical School; Chief, Pulmonary Section, Minneapolis Veterans Affairs Health Care System, Minneapolis, Minnesota
Chronic Obstructive Pulmonary Disease

S. Ragnar Norrby, MD, PhD
Director General, Swedish Institute for Infectious Disease Control, Solna, Sweden
Approach to the Patient with Urinary Tract Infection

David A. Norris, MD
Professor and Chair, Department of Dermatology, University of Colorado Denver School of Medicine, Aurora, Colorado
Structure and Function of the Skin

Susan O'Brien, MD
Professor of Medicine, Department of Leukemia, The University of Texas M.D. Anderson Cancer Center, Houston, Texas
The Chronic Leukemias

Francis G. O'Connor, MD, MPH
Associate Professor, Military and Emergency Medicine, Uniformed Services University, Bethesda, Maryland
Rhabdomyolysis

Patrick G. O'Connor, MD, MPH
Professor of Medicine, Yale University; Chief, General Internal Medicine, Yale University School of Medicine, Yale-New Haven Hospital, New Haven, Connecticut
Alcohol Abuse and Dependence

James R. O'Dell, MD
Professor and Chief of Rheumatology, Department of Internal Medicine, University of Nebraska Medical Center, Omaha, Nebraska
Rheumatoid Arthritis

Anne E. O'Donnell, MD
Professor of Medicine, Chief, Division of Pulmonary, Critical Care, and Sleep Medicine, Georgetown University Hospital, Washington, DC
Bronchiectasis, Atelectasis, Cysts, and Localized Lung Disorders

Jae K. Oh, MD
Professor, Internal Medicine, Co-Director, Echocardiography Laboratory, Division of Cardiovascular Diseases, Mayo Clinic, Rochester, Minnesota
Pericardial Diseases

Jeffrey E. Olgin, MD
Gallo-Chatterjee Distinguished Professor, Chief, Division of Cardiology, Co-Director of the Heart and Vascular Center, University of California, San Francisco, School of Medicine, San Francisco, California
Approach to the Patient with Suspected Arrhythmia

Jeffrey W. Olin, DO
Professor of Medicine, Director Vascular Medicine, Zena and Michael A. Wiener Cardiovascular Institute, Mount Sinai School of Medicine, New York, New York
Other Peripheral Arterial Diseases

Walter A. Orenstein, MD
Deputy Director for Immunization Programs, Vaccine Delivery, Global Health Program, Bill and Melinda Gates Foundation, Seattle, Washington
Immunization

Douglas R. Osmon, MD
Associate Professor of Medicine, Division of Infectious Diseases, Mayo Medical School, Rochester, Minnesota
Infections of Bursae, Joints, and Bones

Catherine M. Otto, MD
J. Ward Kennedy-Hamilton Endowed Chair of Medicine, Director, Training Programs in Cardiovascular Disease, University of Washington School of Medicine; Associate Director, Echocardiography, University of Washington Medical Center, Seattle, Washington
Echocardiography; Videos

Stephen A. Paget, MD
Professor of Medicine, Weill Cornell Medical College; Physician-in-Chief Emeritus, Hospital for Special Surgery, New York, New York
Polymyalgia Rheumatica and Temporal Arteritis

Mark Papania, MD, MPH
Medical Epidemiologist, Division of Viral Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Measles

Peter G. Pappas, MD
Professor of Medicine, Division of Infectious Diseases, University of Alabama School of Medicine, Birmingham, Alabama
Dematiaceous Fungal Infections

Pankaj Jay Pasricha, MD
Professor of Medicine, Chief, Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, California
Gastrointestinal Endoscopy

David L. Paterson, MD
Professor of Medicine, University of Queensland Centre for Clinical Research, Royal Brisbane and Women's Hospital Campus, Brisbane, Australia
Infections due to Other Members of the Enterobacteriaceae, including Management of Multidrug-Resistant Strains

Carlo Patrono, MD
Professor and Chair of Pharmacology, Catholic University School of Medicine, Rome, Italy
Prostaglandins, Aspirin, and Related Compounds

Jean-Michel Pawlotsky, MD, PhD
Professor of Medicine, University of Paris-Est; Director, National Reference Center for Viral Hepatitis B, C and Delta and Department of Virology, Henri Mondor University Hospital; Director, Department of Molecular Virology and Immunology, Institut Mondor de Recherche Biomédicale, Créteil, France
Acute Viral Hepatitis; Chronic Viral and Autoimmune Hepatitis

Richard D. Pearson, MD
Professor of Medicine and Pathology, Division of Infectious Diseases and International Health, University of Virginia School of Medicine, Charlottesville, Virginia
Antiparasitic Therapy

Eli N. Perencevich, MD, MSc
Professor of Internal Medicine, Department of Internal Medicine, University of Iowa, Carver College of Medicine; Core Investigator, Center for Research in the Implementation of Innovative Strategies in Practice, Iowa City Veterans Affairs Medical Center, Iowa City, Iowa
Enterococcal Infections

Trish M. Perl, MD, MSc
Professor, Department of Medicine, Pathology, and Epidemiology, Senior Health System Epidemiologist, Hospital Epidemiology and Infection Control, The Johns Hopkins Health System and University, Baltimore, Maryland
Enterococcal Infections

Michael C. Perry, MD, MSc
Professor of Medicine and Nellie B. Smith Chair of Oncology Emeritus, Departments of Hematology and Medical Oncology, University of Missouri, Ellis Fischel Cancer Center; Medical Director of Clinical Trials, Institute for Clinical and Translational Sciences, University of Missouri, Ellis Fischel Cancer Center, Columbia, Missouri
Approach to the Patient with Cancer

William A. Petri, Jr., MD, PhD
Professor of Medicine, Microbiology and Pathology, Wade Hampton Frost Professor of Epidemiology and Chief, Division of Infectious Diseases and International Health, University of Virginia, Charlottesville, Virginia
Relapsing Fever and Other Borrelia *Infections; African Sleeping Sickness; Amebiasis*

Marc A. Pfeffer, MD, PhD
Dzau Professor of Medicine, Harvard Medical School; Senior Physician, Cardiovascular Division, Brigham and Women's Hospital, Boston, Massachusetts
Heart Failure: Management and Prognosis

Perry J. Pickhardt, MD
Professor of Radiology and Chief, Gastrointestinal Imaging, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
Diagnostic Imaging Procedures in Gastroenterology

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Molecular Genetics), Department of Medicine, Harvard Medical School; Microbiologist, Brigham and Women's Hospital, Boston, Massachusetts
Pseudomonas *and Related Gram-Negative Bacillary Infections*

David S. Pisetsky, MD, PhD
Professor of Medicine and Immunology, Duke University Medical Center; Chief of Rheumatology, Durham Veterans Affairs Medical Center, Durham, North Carolina
Laboratory Testing in the Rheumatic Diseases

Marshall R. Posner, MD
Professor of Medicine and of Gene and Cell Medicine, Director of Head and Neck Medical Oncology, and Director of Office of Cancer Clinical Trials, The Tisch Cancer Institute, Mount Sinai School of Medicine, New York, New York
Head and Neck Cancer

Charlene Prather, MD
Associate Professor of Internal Medicine, Saint Louis University School of Medicine, St. Louis, Missouri
Inflammatory and Anatomic Diseases of the Intestine, Peritoneum, Mesentery, and Omentum

Basil A. Pruitt, Jr., MD
Clinical Professor of Surgery and Dr. Ferdinand P. Herff Chair in Surgery, University of Texas Health Science Center at San Antonio; Consultant Surgeon, U. S. Army Institute of Surgical Research, Fort Sam Houston, San Antonio, Texas
Electric Injury

Reed E. Pyeritz, MD, PhD
Professor of Medicine and Genetics and Vice Chair for Academic Affairs, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Inherited Diseases of Connective Tissue

Thomas C. Quinn, MD, MSc
Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland; Associate Director for International Research, Division of Intramural Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Epidemiology of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Jai Radhakrishnan, MD, MSc
Associate Professor of Clinical Medicine, Department of Medicine, Division of Nephrology; Program Director, Nephrology Fellowship, Division of Nephrology, Columbia University Medical Center, New York, New York
Glomerular Disorders and Nephrotic Syndromes

Ganesh Raghu, MD
Professor of Medicine and Laboratory Medicine (Adjunct), Division of Pulmonary and Critical Care Medicine; Director, Interstitial Lung Disease, Sarcoid and Pulmonary Fibrosis Program; Medical Director, Lung Transplant Program, University of Washington, Seattle, Washington
Interstitial Lung Disease

Margaret V. Ragni, MD, MPH
Professor of Medicine and Clinical and Translational Science, Department of Medicine, Division of Hematology/Oncology, University of Pittsburgh School of Medicine; Director, Hemophilia Center of Western Pennsylvania, Pittsburgh, Pennsylvania
Hemorrhagic Disorders: Coagulation Factor Deficiencies

Srinivasa N. Raja, MD
Professor of Anesthesiology and Neurology; Director, Division of Pain Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Pain

S. Vincent Rajkumar, MD
Professor of Medicine and Chair, Myeloma Amyloidosis Dysproteinemia Group, Division of Hematology, Mayo Medical School and Mayo Clinic, Rochester, Minnesota
Plasma Cell Disorders

Didier Raoult, MD, PhD
Professor, Université de la Méditerranée, National Center for Scientific Research UMR 6236, Research and Development Institute 198, Université de la Méditerranée, Faculté de Médecine, Marseille, France
Bartonella *Species Infections; Rickettsial Infections*

Robert W. Rebar, MD
Volunteer Professor, Department of Obstetrics and Gynecology, Executive Director, American Society for Reproductive Medicine, University of Alabama at Birmingham School of Medicine, Birmingham, Alabama
Ovaries and Development; Reproductive Endocrinology and Infertility

Annette C. Reboli, MD
Professor of Medicine and Vice Dean, Cooper Medical School of Rowan University; Professor of Medicine, University of Medicine and Dentistry of New Jersey/Robert Wood Johnson Medical School, Department of Medicine, Division of Infectious Diseases, Cooper University Hospital, Camden, New Jersey
Erysipelothrix *Infections*

K. Rajender Reddy, MD
Professor of Medicine and of Medicine in Surgery, Director of Hepatology and Medical Director of Liver Transplantation, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Bacterial, Parasitic, Fungal, and Granulomatous Liver Diseases

Donald A. Redelmeier, MD, MSc
Professor of Medicine and of Health Policy Management and Evaluation, University of Toronto; Canada Research Chair, Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada
Postoperative Care and Complications

Susan E. Reef, MD
Medical Epidemiologist, Global Immunization Division, Centers for Disease Control and Prevention, Atlanta, Georgia
Rubella (German Measles)

Neil M. Resnick, MD
Thomas Detre Professor of Medicine and Chief, Division of Gerontology and Geriatric Medicine; Director, University of Pittsburgh Institute on Aging, University of Pittsburgh, Pittsburgh, Pennsylvania
Incontinence

David B. Reuben, MD
Archstone Professor of Medicine; Director, Multicampus Program in Geriatric Medicine and Gerontology; Chief, Division of Geriatrics, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California
Geriatric Assessment

Herbert Y. Reynolds, MD
Professor Emeritus, Department of Medicine, Penn State College of Medicine, Hershey, Pennsylvania; Adjunct Professor of Medicine, Uniformed Services University of the Health Sciences, F. Edward Hebert School of Medicine; Medical Officer, Division of Lung Diseases, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland
Respiratory Structure and Function: Mechanisms and Testing

Emanuel P. Rivers, MD, MPH
Clinical Professor and Senior Staff Attending, Departments of Emergency Medicine and Surgery (Critical Care), Wayne State University; Vice Chairman and Research Director, Department of Emergency Medicine, Henry Ford Hospital, Detroit, Michigan
Approach to the Patient with Shock

Robert A. Rizza, MD
Professor of Medicine, Department of Endocrinology, Mayo Clinic, Rochester, Minnesota
Hypoglycemia/Pancreatic Islet Cell Disorders

Lewis R. Roberts, MB ChB, PhD
Professor, Department of Medicine, Mayo Medical School; Consultant in Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota
Liver and Biliary Tract Tumors

Jean-Marc Rolain, PharmD, PhD
Professor, Université de la Méditerranée, National Center for Scientific Research UMR 6236, Research and Development Institute, Faculté de Médecine et de Pharmacie, Université de la Méditerranée, Marseille, France
Bartonella *Species Infections*

José R. Romero, MD
Professor of Pediatrics, University of Arkansas for Medical Sciences; Horace C. Cabe Professor of Pediatric Infectious Diseases, Arkansas Children's Hospital; Director, Pediatric Infectious Diseases Section; Director, Clinical Trials, Arkansas Children's Hospital Research Institute, Little Rock, Arkansas
Enteroviruses

G. David Roodman, MD, PhD
Professor of Medicine, University of Pittsburgh; Vice Chair for Research, University of Pittsburgh; Director, Center for Bone Biology, University of Pittsburgh Medical Center; University of Pittsburgh Cancer Institute, Pittsburgh, Pennsylvania
Paget's Disease of Bone

Clifford Rosen, MD
Professor, Department of Medicine, Tufts University School of Medicine, Boston, Massachusetts; Senior Scientist, Maine Medical Center Research Institute, Maine Medical Center, Portland, Maine
Osteoporosis

Karen Rosene-Montella, MD
Professor of Medicine and of Obstetrics and Gynecology, Vice Chair of Medicine for Quality and Outcomes, Alpert Medical School at Brown University; Senior Vice President, Women's Services and Clinical Integration, Lifespan; Chief of Medicine, Women and Infants Hospital, Providence, Rhode Island
Common Medical Problems in Pregnancy

Philip J. Rosenthal, MD
Professor, Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, California
Malaria

Marc E. Rothenberg, MD, PhD
Professor of Pediatrics, University of Cincinnati College of Medicine; Director, Division of Allergy and Immunology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Eosinophilic Syndromes

Hope S. Rugo, MD
Clinical Professor of Medicine, Director, Breast Oncology Clinical Trials Program, University of California, San Francisco, Comprehensive Cancer Center, San Francisco, California
Paraneoplastic Syndromes and Other Non-Neoplastic Effects of Cancer

James A. Russell, MD
Professor, Department of Medicine, University of British Columbia; Principal Investigator, James Hogg Research Centre, Institute for Heart and Lung Health, St. Paul's Hospital, Vancouver, British Columbia, Canada
Shock Syndromes Related to Sepsis

Anil K. Rustgi, MD
T. Grier Miller Professor of Medicine and Genetics, Chief of Gastroenterology and American Cancer Society Research Professor, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Neoplasms of the Esophagus and Stomach

Robert A. Salata, MD
Professor and Vice Chair, Department of Medicine; Chief, Division of Infectious Diseases and HIV Medicine, Case Western Reserve University School of Medicine; Attending Physician and Consultant, University Hospitals Case Medical Center, Cleveland, Ohio
Brucellosis

Jane E. Salmon, MD
Professor, Department of Medicine, Weill Cornell Medical College; Collette Kean Research Chair, Divisions of Rheumatology and Research, Hospital for Special Surgery, New York, New York
Mechanisms of Immune-Mediated Tissue Injury

Renato M. Santos, MD
Assistant Professor of Internal Medicine; Associate Director, Cardiovascular Training Program, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Vascular Disorders of the Kidney; Video

Michael N. Sawka, PhD
Chief, Thermal and Mountain Medicine Division, U.S. Army Research Institute of Environmental Medicine, Natick, Massachusetts
Disorders Due to Heat and Cold

Andrew I. Schafer, MD
Chairman, Department of Medicine; The E. Hugh Luckey Distinguished Professor of Medicine, Weill Cornell Medical College; Physician-in-Chief, New York-Presbyterian Hospital/Weill Cornell Medical Center, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Approach to the Patient with Bleeding and Thrombosis; Hemorrhagic Disorders: DIC, Liver Failure, and Vitamin K Deficiency; Thrombotic Disorders: Hypercoagulable States

William Schaffner, MD
Professor and Chair, Department of Preventive Medicine; Professor of Medicine (Infectious Diseases), Vanderbilt University School of Medicine, Nashville, Tennessee
Tularemia and Other Francisella *Infections*

W. Michael Scheld, MD
Bayer-Gerald L. Mandell Professor of Infectious Diseases, Professor of Medicine, Clinical Professor of Neurosurgery, Director, Pfizer Initiative in International Health, Division of Infectious Diseases and International Health, Department of Medicine, University of Virginia Health System, Charlottesville, Virginia
Introduction to Microbial Disease: Host-Pathogen Interactions

Eileen Schneider, MD, MPH
Division of Tuberculosis Elimination, Centers for Disease Control and Prevention, Atlanta, Georgia
Coronaviruses

Thomas J. Schnitzer, MD, PhD
Professor, Physical Medicine, Rehabilitation, and Internal Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Osteoarthritis

Robert T. Schooley, MD
Professor and Head, Division of Infectious Diseases, University of California, San Diego, School of Medicine, San Diego, California
Epstein-Barr Virus Infection

David L. Schriger, MD, MPH
Professor, Department of Emergency Medicine, David Geffen School of Medicine at UCLA, University of California, Los Angeles, California
Approach to the Patient with Abnormal Vital Signs

Steven A. Schroeder, MD
Distinguished Professor of Health and Healthcare, Department of Medicine, and Director, Smoking Cessation Leadership Center, University of California, San Francisco, San Francisco, California
Socioeconomic Issues in Medicine

Lynn M. Schuchter, MD
Professor of Medicine, Chief, Hematology/Oncology Division, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Melanoma and Nonmelanoma Skin Cancers

Sam Schulman, MD, PhD
Professor of Medicine, Department of Medicine, McMaster University, Hamilton, Ontario, Canada
Antithrombotic Therapy

Lawrence B. Schwartz, MD, PhD
Charles and Evelyn Thomas Professor of Medicine, Department of Internal Medicine, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia
Systemic Anaphylaxis, Food Allergy, and Insect Sting Allergy

Robert S. Schwartz, MD
Distinguished Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts
Autoimmune and Intravascular Hemolytic Anemias

Carlos Seas, MD
Associate Professor of Medicine, Cayetano Heredia University; Attending Physician, Department of Tropical and Infectious Diseases, Cayetano Heredia National Hospital, Lima, Peru
Cholera and Other Vibrio *Infections*

Steven A. Seifert, MD
Professor, University of New Mexico School of Medicine; Medical Director, New Mexico Poison and Drug Information Center, Albuquerque, New Mexico
Venomous Snake Bites

Julian L. Seifter, MD
Associate Professor of Medicine, Harvard Medical School; Physician, Brigham and Women's Hospital, Boston, Massachusetts
Potassium Disorders; Acid-Base Disorders

Clay F. Semenkovich, MD
Herbert S. Gasser Professor and Chief, Division of Endocrinology, Metabolism and Lipid Research, Washington University School of Medicine, St. Louis, Missouri
Disorders of Lipid Metabolism

Carol E. Semrad, MD
Associate Professor of Medicine, Section of Gastroenterology, The University of Chicago Pritzker School of Medicine, Chicago, Illinois
Approach to the Patient with Diarrhea and Malabsorption

F. John Service, MD, PhD
Professor of Medicine, Mayo Clinic College of Medicine; Consultant in Endocrinology and Metabolism, Mayo Clinic, Rochester, Minnesota
Hypoglycemia/Pancreatic Islet Cell Disorders

George M. Shaw, MD, PhD
Professor, Division of Hematology/Oncology, Department of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Biology of Human Immunodeficiency Viruses

Pamela J. Shaw, MB ChB, MD
Professor of Neurology, Academic Neurology Unit and Head of Neuroscience Department, University of Sheffield; Director, Sheffield Care and Research Centre for Motor Neuron Disorders, Sheffield, United Kingdom
Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases; Videos

Robert S. Sherwin, MD
CNH Long Professor of Medicine and Chief, Section of Endocrinology; Director, Yale Center for Clinical Investigation, Yale University School of Medicine, New Haven, Connecticut
Type 1 Diabetes Mellitus; Type 2 Diabetes Mellitus

Michael E. Shy, MD
Professor of Neurology and of Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, Michigan
Peripheral Neuropathies; Video

Wilmer L. Sibbitt, Jr., MD
Professor of Internal Medicine, Rheumatology and Neurology, University of New Mexico Health Sciences Center, Albuquerque, New Mexico
Idiopathic Multifocal Fibrosclerosis

Ellen Sidransky, MD
Chief, Section of Molecular Neurogenetics, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland
The Lysosomal Storage Diseases

Robert F. Siliciano, MD, PhD
Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Immunopathogenesis of Human Immunodeficiency Virus Infection

Michael S. Simberkoff, MD
Professor of Medicine, New York University School of Medicine; Chief of Staff, Veterans Affairs New York Harbor Healthcare System, New York, New York
Haemophilus *and* Moraxella *Infections*

David L. Simel, MD, MHS
Professor and Vice Chair for Veterans Affairs, Department of Medicine, Duke University School of Medicine; Chief of Internal Medicine, Department of Medicine Service, Durham Veterans Affairs Medical Center, Durham, North Carolina
Approach to the Patient: History and Physical Examination

Karl Skorecki, MD
Annie Chutick Professor in Medicine (Nephrology) and Director, Rappaport Research Institute, Technion–Israel Institute of Technology; Director of Medical and Research Development, Rambam Health Care Campus, Haifa, Israel
Gene and Cell Therapy; Disorders of Sodium and Water Homeostasis

Arthur S. Slutsky, MD
Professor, Departments of Medicine, Surgery, and Biomedical Engineering, University of Toronto; Vice President of Research, St. Michael's Hospital, Toronto, Ontario, Canada
Acute Respiratory Failure; Mechanical Ventilation; Video

Eric J. Small, MD
Professor of Medicine and Urology, Chief, Division of Hematology and Oncology; Deputy Director and Director of Clinical Sciences, Helen Diller Family Comprehensive Cancer Center, University of California, San Francisco, California
Prostate Cancer

Gerald W. Smetana, MD
Associate Professor of Medicine, Harvard Medical School; Division of General Medicine and Primary Care, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Principles of Medical Consultation

Frederick S. Southwick, MD
Professor of Medicine, Patient Quality Projects Manager, University of Florida and Shands Health System, Gainesville, Florida
Nocardiosis

Robert F. Spiera, MD
Associate Professor of Clinical Medicine, Weill Cornell Medical College; Director, Vasculitis and Scleroderma, The Hospital for Special Surgery, New York, New York
Polymyalgia Rheumatica and Temporal Arteritis

Stanley M. Spinola, MD
Professor and Chair, Department of Microbiology and Immunology; Professor of Medicine and of Pathology and Laboratory Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Chancroid

Pawel Stankiewicz, MD, PhD
Associate Professor, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas
Gene, Genomic, and Chromosomal Disorders

Paul Stark, MD
Professor of Clinical Radiology, University of California, San Diego, and Chief of Cardiothoracic Radiology, Radiology Service, Veterans Affairs San Diego Healthcare System, San Diego, California
Imaging in Pulmonary Disease

APPROACH TO MEDICINE, THE PATIENT, AND THE MEDICAL PROFESSION: MEDICINE AS A LEARNED AND HUMANE PROFESSION

LEE GOLDMAN AND ANDREW I. SCHAFER

APPROACH TO MEDICINE

Medicine is a profession that incorporates science and the scientific method with the art of being a physician. The art of tending to the sick is as old as humanity itself. Even in modern times, the art of caring and comforting, guided by millennia of common sense as well as a more recent, systematic approach to medical ethics (Chapter 2), remains the cornerstone of medicine. Without these humanistic qualities, the application of the modern science of medicine is suboptimal, ineffective, or even detrimental.

The caregivers of ancient times and premodern cultures tried a variety of interventions to help the afflicted. Some of their potions contained what are now known to be active ingredients that form the basis for proven medications (Chapter 28). Others (Chapter 38) have persisted into the present era despite a lack of convincing evidence. Modern medicine should not dismiss the possibility that these unproven approaches may be helpful; instead, it should adopt a guiding principle that all interventions, whether traditional or newly developed, can be tested vigorously, with the expectation that any beneficial effects can be explored further to determine their scientific basis.

When compared with its long and generally distinguished history of caring and comforting, the scientific basis of medicine is remarkably recent. Other than an understanding of human anatomy and the later description, albeit widely contested at this time, of the normal physiology of the circulatory system, almost all of modern medicine is based on discoveries made within the past 150 years. Until the late 19th century, the paucity of medical knowledge was perhaps exemplified best by hospitals and hospital care. Although hospitals provided caring that all but well-to-do people might not be able to obtain elsewhere, there is little if any evidence that hospitals improved health outcomes. The term *hospitalism* referred not to expertise in hospital care but rather to the aggregate of iatrogenic afflictions that were induced by the hospital stay itself.

The essential humanistic qualities of caring and comforting can achieve full benefit only if they are coupled with an understanding of how medical science can and should be applied to patients with known or suspected diseases. Without this knowledge, comforting may be inappropriate or misleading, and caring may be ineffective or counterproductive if it inhibits a sick person from obtaining appropriate, scientific medical care. *Goldman's Cecil Textbook of Medicine* focuses on the discipline of *internal medicine,* from which neurology and dermatology, which are also covered in substantial detail in this text, are relatively recent evolutionary branches. The term *internal medicine,* which is often misunderstood by the lay public, was developed in 19th-century Germany. *Inneren medizin* was to be distinguished from clinical medicine because it emphasized the physiology and chemistry of disease, not just the patterns or progression of clinical manifestations. *Goldman's Cecil Textbook of Medicine* follows this tradition by showing how pathophysiologic abnormalities cause symptoms and signs and by emphasizing how therapies can modify the underlying pathophysiology and improve the patient's well-being.

Modern medicine has moved rapidly past organ physiology to an increasingly detailed understanding of cellular, subcellular, and genetic mechanisms. For example, the understanding of microbial pathogenesis and many inflammatory diseases (Chapter 264) is now guided by a detailed understanding of the human immune system and its response to foreign antigens (Chapters 44 to 48).

Health, disease, and an individual's interaction with the environment are also substantially determined by genetics. In addition to many conditions that may be determined by a single gene (Chapter 40), medical science increasingly understands the complex interactions that underlie multigenic traits (Chapter 41). In the not-so-distant future, the decoding of the human genome holds the promise that personalized health care can be targeted according to an individual's genetic profile, in terms of screening and presymptomatic disease management, as well as in terms of specific medications and their adjusted dosing schedules. Currently, knowledge of the structure and physical forms of proteins helps explain abnormalities as diverse as sickle cell anemia (Chapter 166) and prion-related diseases (Chapter 424). Proteomics, which is the normal and abnormal protein expression of genes, also holds extraordinary promise for developing drug targets for more specific and effective therapies.

Concurrent with these advances in fundamental human biology has been a dramatic shift in methods for evaluating the application of scientific advances to the individual patient and to populations. The randomized controlled trial, sometimes with thousands of patients at multiple institutions, has replaced anecdote as the preferred method for measuring the benefits and optimal uses of diagnostic and therapeutic interventions (Chapter 9). As studies progress from those that show biologic effect, to those that elucidate dosing schedules and toxicity, and finally to those that assess true clinical benefit, the metrics of measuring outcome has also improved from subjective impressions of physicians or patients to reliable and valid measures of morbidity, quality of life, functional status, and other patient-oriented outcomes (Chapter 10). These marked improvements in the scientific methodology of clinical investigation have expedited extraordinary changes in clinical practice, such as recanalization therapy for acute myocardial infarction (Chapter 73), and have shown that reliance on intermediate outcomes, such as a reduction in asymptomatic ventricular arrhythmias with certain drugs, may unexpectedly increase rather than decrease mortality. Just as physicians in the 21st century must understand advances in fundamental biology, similar understanding of the fundamentals of clinical study design as it applies to diagnostic and therapeutic interventions is needed. An understanding of human genetics will also help stratify and refine the approach to clinical trials by helping researchers select fewer patients with a more homogeneous disease pattern to study the efficacy of an intervention.

This explosion in medical knowledge has led to increasing specialization and subspecialization, defined initially by organ system and more recently by locus of principal activity (inpatient vs. outpatient), reliance on manual skills (proceduralist vs. nonproceduralist), or participation in research. Nevertheless, it is becoming increasingly clear that the same fundamental molecular and genetic mechanisms are broadly applicable across all organ systems and that the scientific methodologies of randomized trials and careful clinical observation span all aspects of medicine.

The advent of modern approaches to managing data now provides the rationale for the use of health information technology. Computerized health records, oftentimes shared with patients in a portable format, can avoid duplication of tests and assure that care is coordinated among the patient's various health care providers.

APPROACH TO THE PATIENT

Patients commonly have complaints (symptoms). These symptoms may or may not be accompanied by abnormalities on examination (signs) or on laboratory testing. Conversely, asymptomatic patients may have signs or laboratory abnormalities, and laboratory abnormalities can occur in the absence of symptoms or signs.

Symptoms and signs commonly define *syndromes,* which may be the common final pathway of a wide range of pathophysiologic alterations. The fundamental basis of internal medicine is that diagnosis should elucidate the pathophysiologic explanation for symptoms and signs so that therapy may improve the underlying abnormality, not just attempt to suppress the abnormal symptoms or signs.

When patients seek care from physicians, they may have manifestations or exacerbations of known conditions, or they may have symptoms and signs that suggest malfunction of a particular organ system. Sometimes the pattern of symptoms and signs is highly suggestive or even pathognomonic for a particular disease process. In these situations, in which the physician is focusing on a particular disease, *Goldman's Cecil Textbook of Medicine* provides scholarly yet practical approaches to the epidemiology, pathobiology, clinical manifestations, diagnosis, treatment, prevention, and prognosis of entities such as acute myocardial infarction (Chapter 73), chronic obstructive lung disease (Chapter 88), obstructive uropathy (Chapter 125), inflammatory bowel disease (Chapter 143), gallstones (Chapter 158), rheumatoid arthritis (Chapter 272), hypothyroidism (Chapter 233), tuberculosis (Chapter 332), and virtually any known medical condition in adults.

Many patients, however, have undiagnosed symptoms, signs, or laboratory abnormalities that cannot be immediately ascribed to a particular disease or cause. Whether the initial manifestation is chest pain (Chapter 50), diarrhea (Chapter 142), neck or back pain (Chapter 407), or a variety of more than 100 common symptoms, signs, or laboratory abnormalities, *Goldman's Cecil Textbook of Medicine* provides tables, figures, and entire chapters to guide the approach to diagnosis and therapy (see E-Table 1-1 or table on inside back cover). By virtue of this dual approach to known disease as well as to undiagnosed abnormalities, this textbook, similar to the modern practice of medicine, applies directly to patients regardless of their mode of manifestation or degree of previous evaluation.

The patient-physician interaction proceeds through many phases of clinical reasoning and decision making. The interaction begins with an elucidation of complaints or concerns, followed by inquiries or evaluations to address these concerns in increasingly precise ways. The process commonly requires a careful history or physical examination, ordering of diagnostic tests, integration of clinical findings with test results, understanding of the risks and benefits of the possible courses of action, and careful consultation with the patient and family to develop future plans. Physicians can increasingly call on a growing literature of evidence-based medicine to guide the process so that benefit is maximized while respecting individual variations in different patients. Throughout *Goldman's Cecil Textbook of Medicine,* the best current evidence is highlighted with specific grade A references that can be accessed directly in the electronic version.

The increasing availability of evidence from randomized trials to guide the approach to diagnosis and therapy should not be equated with "cookbook" medicine. Evidence and the guidelines that are derived from it emphasize proven approaches for patients with specific characteristics. Substantial clinical judgment is required to determine whether the evidence and guidelines apply to individual patients and to recognize the occasional exceptions. Even more judgment is required in the many situations in which evidence is absent or inconclusive. Evidence must also be tempered by patients' preferences, although it is a physician's responsibility to emphasize evidence when presenting alternative options to the patient. The adherence of a patient to a specific regimen is likely to be enhanced if the patient also understands the rationale and evidence behind the recommended option.

To care for a patient as an individual, the physician must understand the patient as a person. This fundamental precept of doctoring includes an understanding of the patient's social situation, family issues, financial concerns, and preferences for different types of care and outcomes, ranging from maximum prolongation of life to the relief of pain and suffering (Chapters 2 and 3). If the physician does not appreciate and address these issues, the science of medicine cannot be applied appropriately, and even the most knowledgeable physician will fail to achieve the desired outcomes.

Even as physicians become increasingly aware of new discoveries, patients can obtain their own information from a variety of sources, some of which are of questionable reliability. The increasing use of alternative and complementary therapies (Chapter 38) is an example of patients' frequent dissatisfaction with prescribed medical therapy. Physicians should keep an open mind regarding unproven options but must advise their patients carefully if such options may carry any degree of potential risk, including the risk that they may be relied on to substitute for proven approaches. It is crucial for the physician to have an open dialogue with the patient and family regarding the full range of options that either may consider.

The physician does not exist in a vacuum, but rather as part of a complicated and extensive system of medical care and public health. In premodern times and even today in some developing countries, basic hygiene, clean water, and adequate nutrition have been the most important ways to promote health and reduce disease. In developed countries, adoption of healthy lifestyles, including better diet (Chapter 220) and appropriate exercise (Chapter 15), is the cornerstone to reducing the epidemics of obesity (Chapter 227), coronary disease (Chapter 70), and diabetes (Chapter 237). Public health interventions to provide immunizations (Chapter 17) and to reduce injuries and the use of tobacco (Chapter 31), illicit drugs (Chapter 33), and excess alcohol (Chapter 32) can collectively produce more health benefits than nearly any other imaginable health intervention.

APPROACH TO THE MEDICAL PROFESSION

In a profession, practitioners put the welfare of clients or patients above their own welfare. Professionals have a duty that may be thought of as a contract with society. The American Board of Internal Medicine and the European Federation of Internal Medicine have jointly proposed that medical professionalism should emphasize three fundamental principles: the primacy of patient welfare, patient autonomy, and social justice. As modern medicine brings a plethora of diagnostic and therapeutic options, the interactions of the physician with the patient and society become more complex and potentially fraught with ethical dilemmas (Chapter 2). To help provide a moral compass that is not only grounded in tradition but also adaptable to modern times, the primacy of patient welfare emphasizes the fundamental principle of a profession. The physician's altruism, which begets the patient's trust, must be impervious to the economic, bureaucratic, and political challenges that are faced by the physician and the patient (Chapter 5).

TABLE 1-1 PROFESSIONAL RESPONSIBILITIES

Commitment to:
Professional competence
Honesty with patients
Patient confidentiality
Maintaining appropriate relations with patients
Improving the quality of care
Improving access to care
Just distribution of finite resources
Scientific knowledge
Maintaining trust by managing conflicts of interest
Professional responsibilities

From Brennan T, Blank L, Cohen J, et al. Medical professionalism in the new millennium: a physician charter. *Ann Intern Med.* 2002;1136:243-246.

The principle of patient autonomy asserts that physicians make recommendations but patients make the final decisions. The physician is an expert advisor who must inform and empower the patient to base decisions on scientific data and how these data can and should be integrated with a patient's preferences.

The importance of social justice symbolizes that the patient-physician interaction does not exist in a vacuum. The physician has a responsibility to the individual patient and to broader society to promote access and to eliminate disparities in health and health care.

To promote these fundamental principles, a series of professional responsibilities has been suggested (Table 1-1). These specific responsibilities represent practical, daily traits that benefit the physician's own patients and society as a whole. Physicians who use these and other attributes to improve their patients' satisfaction with care are not only promoting professionalism but also reducing their own risk for liability and malpractice.

An interesting new aspect of professionalism is the increasing reliance on team approaches to medical care, as exemplified by physicians whose roles are defined by the location of their practice—historically in the intensive care unit or emergency department and more recently on the inpatient general hospital floor. Quality care requires coordination and effective communication across inpatient and outpatient sites among physicians who themselves now typically work defined hours. This transition from reliance on a single, always available physician to a team, ideally with a designated coordinator, places new challenges on physicians, the medical care system, and the medical profession.

The changing medical care environment is placing increasing emphasis on standards, outcomes, and accountability. As purchasers of insurance become more cognizant of value rather than just cost (Chapter 11), outcomes ranging from rates of screening mammography (Chapter 204) to mortality rates with coronary artery bypass graft surgery (Chapter 74) become metrics by which rational choices can be made. Clinical guidelines and critical pathways derived from randomized controlled trials and evidence-based medicine can potentially lead to more cost-effective care and better outcomes.

These major changes in many Western health care systems bring with them many major risks and concerns. If the concept of limited choice among physicians and health care providers is based on objective measures of quality and outcome, channeling of patients to better providers is one reasonable definition of better selection and enlightened competition. If the limiting of options is based overwhelmingly on cost rather than measures of quality, outcomes, and patient satisfaction, it is likely that the historic relationship between the patient and the truly professional physician will be fundamentally compromised.

Another risk is that the same genetic information that could lead to more effective, personalized medicine will be used against the very people whom it is supposed to benefit—by creating a stigma, raising health insurance costs, or even making someone uninsurable. The ethical approach to medicine

(Chapter 2), genetics, and genetic counseling (Chapter 39) provides means to protect against this adverse effect of scientific progress.

In this new environment, the physician often has a dual responsibility: to the health care system as an expert who helps create standards, measures of outcome, clinical guidelines, and mechanisms to ensure high-quality, cost-effective care and to individual patients who entrust their well-being to that physician to promote their best interests within the reasonable limits of the system. A health insurance system that emphasizes cost-effective care, that gives physicians and health care providers responsibility for the health of a population and the resources required to achieve these goals, that must exist in a competitive environment in which patients can choose alternatives if they are not satisfied with their care, and that places increasing emphasis on health education and prevention can have many positive effects. In this environment, however, physicians must beware of overt and subtle pressures that could entice them to underserve patients and abrogate their professional responsibilities by putting personal financial reward ahead of their patients' welfare. The physician's responsibility to represent the patient's best interests and avoid financial conflicts by doing too little in the newer systems of capitated care provides different specific challenges but an analogous moral dilemma to the historical American system in which the physician could be rewarded financially for doing too much.

In the current health care environment, all physicians and trainees must redouble their commitment to professionalism. At the same time, the challenge to the individual physician to retain and expand the scientific knowledge base and process the vast array of new information is daunting. In this spirit of a profession based on science and caring, *Goldman's Cecil Textbook of Medicine* seeks to be a comprehensive approach to modern internal medicine.

2

BIOETHICS IN THE PRACTICE OF MEDICINE

EZEKIEL J. EMANUEL

It commonly is argued that modern advances in medical technology, antibiotics, dialysis, transplantation, and intensive care units have created the bioethical dilemmas that confront physicians in the 21st century. In reality, however, concerns about ethical issues are as old as the practice of medicine itself. The Hippocratic Oath, composed sometime around 400 BC, attests to the need of ancient Greek physicians for advice on how to address the many bioethical dilemmas that they confronted. The Oath addresses issues of confidentiality, abortion, euthanasia, sexual relations between physician and patient, divided loyalties, and, at least implicitly, charity care and executions. Other Hippocratic works address issues such as termination of treatments to dying patients and telling the truth. Whether we agree with the advice dispensed or not, the important point is that many bioethical issues are not created by technology but are inherent in medical practice. Technology may make these issues more common and may change the context in which they arise, but there are underlying bioethical issues that seem timeless, inherent in the practice of medicine.

Many physicians have been educated that four main principles can be invoked to address bioethical dilemmas: autonomy, nonmaleficence, beneficence, and justice. Autonomy is the idea that people should have the right and freedom to choose, pursue, and revise their own life plans. Nonmaleficence is the idea that people should not be harmed or injured knowingly; this principle is encapsulated in the frequently repeated phrase that a physician has an obligation to "first do no harm"—*primum non nocere*. This phrase is not found either in the Hippocratic Oath or in other Hippocratic writing; the only related, but not identical, Hippocratic phrase is "at least, do not harm." Whereas nonmaleficence is about avoiding harm, beneficence is about the positive actions that the physician should undertake to promote the well-being of his or her patients. In clinical practice, this obligation usually arises from the implicit and explicit commitments and promises surrounding the physician-patient relationship. Finally, there is the principle of justice as the fair distribution of benefits and burdens.

Although helpful in providing an initial framework, these principles have limited value because they are broad and open to diverse and conflicting interpretations. In addition, as is clear with the principle of justice, they frequently are underdeveloped. In any difficult case, the principles are likely to conflict. Conflicting ethical principles are precisely why there are bioethical dilemmas. The principles themselves do not offer guidance on how they should be balanced or specified to resolve the dilemma. These principles, which are focused on the individual physician-patient context, are not particularly helpful when the bioethical issues are institutional and systemic, such as allocating scarce vaccines or organs for transplantation or balancing the risks and benefits of mammograms for women younger than 50 years. Finally, these four principles are not comprehensive. Other fundamental ethical principles and values, such as communal solidarity, duties to future generations, trust, and professional integrity, are important in bioethics but not encapsulated except by deformation in these four principles.

There is no formula or small set of ethical principles that mechanically or magically gives answers to bioethical dilemmas. Instead, medical practitioners should follow an orderly analytic process. First, practitioners need to obtain the facts relevant to the situation. Second, they must delineate the basic bioethical issue. Third, it is important to identify all the crucial principles and values that relate to the case and how they might conflict. Fourth, because many ethical dilemmas have been analyzed previously and subjected frequently to empirical study, practitioners should examine the relevant literature, whether it is commentaries or studies in medical journals, legal cases, or books. With these analyses, the particular dilemma should be reexamined; this process might lead to reformulation of the issue and identification of new values or new understandings of existing values. Fifth, with this information, it is important to distinguish clearly unethical practices from a range of ethically permissible actions. Finally, it is important not only to come to some resolution of the case but also to state clearly the reasons behind the decisions, that is, the interpretation of the principles used and how values were balanced. Although unanimity and consensus may be desirable ideals, reasonable people frequently disagree about how to resolve ethical dilemmas without being unethical or malevolent.

A multitude of bioethical dilemmas arise in medical practice, including issues of genetics, reproductive choices, and termination of care. In clinical practice, the most common issues revolve around informed consent, termination of life-sustaining treatments, euthanasia and physician-assisted suicide, and conflicts of interest.

PHYSICIAN-PATIENT RELATIONSHIP: INFORMED CONSENT

History

It commonly is thought that the requirement for informed consent is a relatively recent phenomenon. Suggestions about the need for a patient's informed consent can be found as far back as Plato, however. The first recorded legal case involving informed consent is the 1767 English case of *Slater v. Baker and Stapleton,* in which two surgeons refractured a patient's leg after it had healed improperly. The patient claimed they had not obtained consent. The court ruled:

> *[I]t appears from the evidence of the surgeon that it was improper to disunite the callous without consent; this is the usage and law of surgeons: then it was ignorance and unskillfulness in that very particular, to do contrary to the rule of the profession, what no surgeon ought to have done.*

Although there may be some skepticism about the extent of the information disclosed or the precise nature of the consent obtained, the notable fact is that an 18th-century court declared that obtaining prior consent of the patient is not only the usual practice but also the ethical and legal obligation of surgeons. Failure to obtain consent is incompetent and inexcusable. In contemporary times, the 1957 case of *Salgo v. Leland Stanford Junior University Board of Trustees* constitutes a landmark by stating that physicians have a

positive legal obligation to disclose information about risks, benefits, and alternatives to patients; this decision popularized the term *informed consent.*

Definition and Justification

Informed consent is a person's autonomous authorization of a physician to undertake diagnostic or therapeutic interventions for himself or herself. In this view, the patient understands that he or she is taking responsibility for the decision while empowering someone else, the physician, to implement it. Not any agreement to a course of medical treatment qualifies as informed consent, however.

There are four fundamental requirements for valid informed consent: mental capacity, disclosure, understanding, and voluntariness. Informed consent assumes that people have the mental capacity to make decisions; disease, development, or medications can compromise patients' mental capacity to provide informed consent. Adults are presumed to have the legal competence to make medical decisions, and whether an adult is incompetent to make medical decisions is a legal determination. Practically, physicians usually decide whether patients are competent on the basis of whether patients can understand the information disclosed, appreciate its significance for their own situation, and use logical and consistent thought processes in decision making. Incompetence in medical decision making does not mean a person is incompetent in all types of decision making and vice versa. Crucial information relevant to the decision must be disclosed, usually by the physician, to the patient. The patient should understand the information and its implications for his or her interests and life goals. Finally, the patient must make a voluntary decision (i.e., one without coercion or manipulation by the physician). It is a mistake to view informed consent as an event, such as the signing of a form. Informed consent is viewed more accurately as a process that evolves during the course of diagnosis and treatment.

Typically, the patient's autonomy is the value invoked to justify informed consent. Other values, such as bodily integrity and beneficence, have also been cited, especially in early legal rulings.

Empirical Data

Fairly extensive research has been done on informed consent. In general, studies show that in clinical situations, physicians frequently do not communicate all relevant information for informed decision making. In a study of audiotapes from 1057 outpatient encounters, physicians mentioned alternatives in only 11.3% of cases, provided pros and cons of interventions in only 7.8% of situations, and assessed the patient's understanding of the information in only 1.5% of decisions. The more complex the medical decisions, the more likely it was that the elements of informed consent would be fulfilled. Importantly, data suggest that disclosure is better in research settings, both in the informed consent documents and in the discussions. For instance, in recorded interactions between researchers and prospective participants, the major elements of research, such as that the treatment was investigational and the risks and benefits, were disclosed in more than 80% of interactions. Greater disclosure in the research setting may be the consequence of requiring a written informed consent document. Some have suggested that for common medical interventions, such as elective surgery, standardized informed consent documents should include the risks and benefits as quantified in randomized controlled trials, as well as acceptable alternatives.

Patients frequently fail to recall crucial information disclosed, although they usually think they have sufficient information for decision making. Whether patients fail to recall key information because they are overwhelmed by the information or because they do not find much of it salient to their decision is unclear. The issue is what patients understand at the point of decision making, not what they recall later.

Studies aimed at improving informed consent in the clinical setting suggest that interactive media, such as videos, can improve understanding by patients. Conversely, data from the research setting suggest that interactive media do not improve participants' understanding, whereas more personal interaction, whether as an additional telephone call by a research nurse or as an additional face-to-face meeting, does enhance understanding.

One of the most important results of empirical research on informed consent is the gap between information and decision making. Many studies show that most patients want information, but far fewer prefer decision-making authority. One study showed that most patients wanted information, but only about one third desired decision-making authority, and patients' decision-making preferences were not correlated with their information-seeking preferences. Several investigators found that patients' preference for decision-making authority increases with higher educational levels and declines with advancing age. Most important, the more serious the illness, the more likely patients are to prefer that physicians make the decisions. Several studies suggest that patients who have less of a desire to make their own decisions generally are more satisfied with how the decisions were made.

TABLE 2-1 FUNDAMENTAL ELEMENTS FOR DISCLOSURE TO PATIENTS

Diagnosis and prognosis
Nature of proposed intervention
Reasonable alternative interventions
Risks associated with each alternative intervention
Benefits associated with each alternative intervention
Probable outcomes of each alternative intervention

Practical Considerations

Implementing informed consent raises concerns about the extent of information to be disclosed and exceptions to the general requirement. A major area of ethical and legal disagreement has been what information to disclose and how to disclose it. As a practical matter, physicians should disclose at least six fundamental elements of information to patients: (1) diagnosis and prognosis; (2) nature of the proposed intervention; (3) alternative interventions, including no treatment; (4) risks associated with each alternative; (5) benefits of each alternative; and (6) likely outcomes of these alternatives (Table 2-1). Because risk is usually the key worry of physicians, it generally is recommended that physicians disclose (1) the nature of the risks, (2) their magnitude, (3) the probability that each risk will occur, and (4) when the consequence might occur. Some argue that minor risks need not be disclosed. In general, all serious risks, such as death, paralysis, stroke, or chronic pain, even if rare, should be disclosed, as should common risks.

The central problem is that the physician should provide this detailed information within reasonable time constraints and yet not overwhelm patients with complex information in technical language. The result has been various legal standards defining how much information should be disclosed. The *physician* or *customary* standard, adapted from malpractice law, states that the physician should disclose information "which a reasonable medical practitioner would make under the same or similar circumstances." Conversely, the *reasonable person* or *lay-oriented* standard states that physicians should disclose all information that a "reasonable person in the patient's circumstances would find material to" the medical decision. The physician standard is factual and can be determined empirically, but the patient-oriented standard, which is meant to engage physicians with patients, is hypothetical. Currently, each standard is used by about half the states.

There are exceptions to the requirements of informed consent. In emergency situations, consent can be assumed because patients' interests concentrate on survival and retaining maximal mental and physical functioning; as a result, reasonable persons would want treatment. In some circumstances, physicians may believe the process of informed consent could pose a serious psychological threat. In rare cases, the "therapeutic privilege" promoting a patient's well-being trumps autonomy, but physicians should be wary of invoking this exception too readily.

If patients are deemed incompetent, family members—beginning with spouse, children, parents, siblings, then more distant relatives—usually are selected as surrogates or proxies, although there may be concerns about conflicting interests or knowledge of the patient's wishes. In the relatively rare circumstance in which a patient formally designated a proxy, that person has decision-making authority.

The *substituted judgment* standard states that the proxy should choose what the patient would choose if he or she were competent. The *best interests* standard states that the proxy should choose what is best for the patient. Frequently, it is not clear how the patient would have decided because the situation was not discussed with the patient and he or she left no living will. Similarly, what is best for a patient is controversial because there are usually tradeoffs between quality of life and survival. These problems are exacerbated because a proxy's predictions about a patient's quality of life are poor; proxies tend to underestimate patients' functional status and satisfaction. Similarly, proxy predictions are inaccurate regarding life-sustaining preferences when the patient is mentally incapacitated; families tend to agree with patients less than 70% of the time in deciding whether to provide life-sustaining treatments if the patient became demented, when chance alone would generate

agreement in 50% of the cases. Such confusion about how to decide for incapacitated patients can create conflicts among family members or between the family and medical providers. In such circumstances, an ethics consultation may be helpful.

TERMINATION OF MEDICAL INTERVENTIONS

History

Since the start of medicine, it has been viewed as ethical to withhold medical treatments from the terminally ill and "let nature take its course." Hippocrates argued that physicians should "refuse to treat those [patients] who are overmastered by their disease." In the 19th century, prominent American physicians advocated withholding of cathartic and emetic "treatments" from the terminally ill and using ether to ease pain at the end of life. In 1900, editors of *The Lancet* argued that physicians should intervene to ease the pain of death but did not have an obligation to prolong a clearly terminal life. The contemporary debate on terminating care began in 1976 with the *Quinlan* case, in which the New Jersey Supreme Court ruled that patients had a right to refuse life-sustaining interventions on the basis of a right of privacy and that the family could exercise the right for a patient in a persistent vegetative state.

Definition and Justification

It generally is agreed that all patients have a right to refuse medical interventions. Ethically, this right is based on the patient's autonomy and is implied by the doctrine of informed consent. Legally, state courts have cited the right to privacy, right to bodily integrity, or common law to justify the right to refuse medical treatment. In the 1990 *Cruzan* case and in the subsequent physician-assisted suicide cases, the U.S. Supreme Court affirmed that there is a "constitutionally protected right to refuse lifesaving hydration and nutrition." The Court stated that "[A] liberty interest [based on the 14th Amendment] in refusing unwanted medical treatment may be inferred from our prior decisions." All patients have a constitutional and an ethical right to refuse medical interventions. These rulings were the basis of the consistent state and federal court rulings to permit the husband to terminate artificial nutrition and hydration in the *Schiavo* case.

Empirical Data

Data show that termination of medical treatments is now the norm. More than 85% of Americans die without cardiopulmonary resuscitation, and more than 90% of decedents in intensive care units do not receive cardiopulmonary resuscitation. Of decedents in intensive care units, 90% die after the withholding or withdrawal of medical treatments, with an average of 2.6 interventions being withheld or withdrawn per decedent. Since the 1990s, the trend has been to stop medical interventions more frequently.

Despite extensive public support for use of advance care directives and the passage of the Patient Self-Determination Act mandating that health care institutions inform patients of their right to complete such documents, only about 47% of Americans have completed one. Data suggest that over 40% of patients required active decision-making about terminating medical treatments in their final days, yet 70% lack decision-making capacity, thereby emphasizing the importance of advance directives. Efforts to improve completion of advance care directives have generated mixed results. Unfortunately, even successful pilot efforts have not been adopted or easily scaled. A persistent problem has been that even when patients complete advance care directives, the documents frequently are not available, physicians do not know they exist, or they tend to be too general or vague to guide decisions. The widespread use of electronic health records should create the possibility that advance directives will be available whenever the patient presents to a health care provider.

Just as proxies are poor at predicting patients' wishes, data show that physicians are probably even worse at determining patients' preferences for life-sustaining treatments. In many cases, life-sustaining treatments are continued even when patients or their proxies desire them to be stopped; conversely, many physicians discontinue or never begin interventions unilaterally without the knowledge or consent of patients or their surrogate decision makers. These discrepancies emphasize the importance of engaging patients early in their care about treatment preferences.

Practical Considerations

There are many practical considerations in enacting this right (Table 2-2). First, patients have a right to refuse any and all medical interventions, from blood transfusions and antibiotics to respirators, artificial hydration, and nutrition. Although initiation of cardiopulmonary resuscitation was the focus of the early court cases, this issue is viewed best as addressing just one of the many medical interventions that can be stopped or withheld. The attempt to distinguish ordinary from extraordinary or heroic treatments has been unhelpful in determining which treatments may be stopped.

Second, there is no ethical or legal difference between withholding an intervention and withdrawing it. If a respirator or other treatment is started because physicians are uncertain whether a patient would have wanted it, they always can stop it later when information clarifies the patient's wishes. Although physicians and nurses might find stopping a treatment to be more difficult psychologically, withdrawal is ethically and legally permitted—and required—when it is consonant with the patient's wishes.

Third, competent patients have the exclusive right to decide about terminating their own care. If there is a conflict between a competent patient and his or her family, the patient's wishes are to be followed. It is the patient's right to refuse treatment, not the family's right. For incompetent patients, the situation is more complex; if the patients left clear indications of their wishes, whether as explicit oral statements or as written advance care directives, these wishes should be followed. Physicians should not be overly concerned about the precise form patients use to express their wishes; because patients have a constitutional right to refuse treatment, the real concern is whether the wishes are clear and relevant to the situation. If an incompetent patient did not leave explicit indications of his or her wishes or designate a proxy decision maker, the physician should identify a surrogate decision maker and rely on the decision maker's wishes while being cognizant of the potential problems noted.

Fourth, the right to refuse medical treatment does not translate into a right to demand any treatment, especially treatments that have no pathophysiologic rationale, have already failed, or are known to be harmful. Futility has become a justification to permit physicians unilaterally to withhold or withdraw treatments despite the family's requests for treatment. Some states, such as Texas, have enacted futility laws, which prescribe procedures by which

TABLE 2-2 PRACTICAL CONSIDERATIONS IN TERMINATION OF MEDICAL TREATMENTS

PRACTICAL QUESTION	ANSWER
Is there a legal right to refuse medical interventions?	Yes. The U.S. Supreme Court declared that competent people have a constitutionally protected right to refuse unwanted medical treatments based on the 14th Amendment.
What interventions can be legally and ethically terminated?	Any and all interventions (including respirators, antibiotics, intravenous or enteral nutrition, and hydration) can be legally and ethically terminated.
Is there a difference between withholding life-sustaining interventions and withdrawing them?	No. The consensus is that there is no important legal or ethical difference between withholding and withdrawing medical interventions. Stopping a treatment once begun is just as ethical as never having started it.
Whose view about terminating life-sustaining interventions prevails if there is a conflict between the patient and family?	The views of a competent adult patient prevail. It is the patient's body and life.
Who decides about terminating life-sustaining interventions if the patient is incompetent?	If the patient appointed a proxy or surrogate decision maker when competent, that person is legally empowered to make decisions about terminating care. If no proxy was appointed, there is a legally designated hierarchy, usually (1) spouse, (2) adult children, (3) parents, (4) siblings, and (5) available relatives.
Are advance care directives legally enforceable?	Yes. As a clear expression of the patient's wishes, they are a constitutionally protected method for patients to exercise their right to refuse medical treatments. In almost all states, clear and explicit oral statements are legally and ethically sufficient for decisions about withholding or withdrawing medical interventions.

TABLE 2-3 DEFINITIONS OF ASSISTED SUICIDE AND EUTHANASIA

TERM	DEFINITION
Voluntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death with the patient's informed consent
Involuntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death when the patient was competent to consent but did not (e.g., the patient may not have been asked)
Nonvoluntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death when the patient was incompetent and was mentally incapable of consenting (e.g., the patient might have been in a coma)
Passive euthanasia	Withholding or withdrawal of life-sustaining medical treatments from a patient to let him or her die (termination of life-sustaining treatments)
Indirect euthanasia	Administration of narcotics or other medications to relieve pain with the incidental consequence of causing sufficient respiratory depression to result in the patient's death
Physician-assisted suicide	A physician provides medications or other interventions to a patient with the understanding that the patient can use them to commit suicide

physicians can invoke futility either to transfer a patient or to terminate interventions. However, the principle of futility is not easy to implement in medical practice. Initially, some commentators advocated that an intervention was futile when the probability of success was 1% or lower. Although this threshold seems to be based on empirical data, it is a covert value judgment. Because the declaration of futility is meant to justify unilateral determinations by physicians, it generally has been viewed as an inappropriate assertion that undermines physician-patient communication and violates the principle of shared decision making. Similar to the distinction between ordinary and extraordinary, futility is viewed increasingly as more obfuscating than clarifying, and it is being invoked much less often.

ASSISTED SUICIDE AND EUTHANASIA

History

Since Hippocrates, euthanasia and physician-assisted suicide have been controversial issues. In 1905, a bill was introduced into the Ohio legislature to legalize euthanasia; it was defeated. In the mid-1930s, similar bills were introduced and defeated in the British Parliament and the Nebraska legislature. As of 2010, physician-assisted suicide is legal in Oregon and Washington State, based on state-wide public referenda, and euthanasia and physician-assisted suicide are legal in the Netherlands, Belgium, Luxembourg, and Switzerland. Recently, the Montana Supreme Court did not recognize a constitutional right to physician-assisted suicide, but it ruled that the law permitting the termination of life-sustaining treatment protected physicians from prosecution if they helped hasten the death of a consenting, rational, terminally ill patient.

Definition and Justification

The terms *euthanasia* and *physician-assisted suicide* require careful definition (Table 2-3). So-called passive and indirect euthanasia are misnomers and are not instances of euthanasia, and both are deemed ethical and legal.

There are four arguments against permitting euthanasia and physician-assisted suicide. First, Kant and Mill thought that autonomy did not permit the voluntary ending of the conditions necessary for autonomy, and as a result, both philosophers were against voluntary enslavement and suicide. Consequently, the exercise of autonomy cannot include the ending of life because that would mean ending the possibility of exercising autonomy. Second, many dying patients may have pain and suffering because they are not receiving appropriate care, and it is possible that adequate care would relieve much pain and suffering (Chapter 3). Although a few patients still may experience uncontrolled pain and suffering despite optimal end-of-life care, it is unwise to use the condition of these few patients as a justification to permit euthanasia or physician-assisted suicide for any dying patient. Third, there is a clear distinction between intentional ending of a life and termination of life-sustaining treatments. The actual acts are different—injecting a life-ending medication, such as a muscle relaxant, or providing a prescription for one is not the same as removing or refraining from introducing an invasive medical intervention. Finally, adverse consequences of permitting euthanasia and physician-assisted suicide must be considered. There are disturbing reports of involuntary euthanasia in the Netherlands, and many worry about coercion of expensive or burdensome patients to accept euthanasia or physician-assisted suicide. Permitting euthanasia and physician-assisted suicide is likely to lead to further intrusions of lawyers, courts, and legislatures into the physician-patient relationship.

There are four parallel arguments for permitting euthanasia and physician-assisted suicide. First, it is argued that autonomy justifies euthanasia and physician-assisted suicide. To respect autonomy requires permitting individuals to decide when it is better to end their lives by euthanasia or physician-assisted suicide. Second, beneficence—furthering the well-being of individuals—supports permitting euthanasia and physician-assisted suicide. In some cases, living can create more pain and suffering than death; ending a painful life relieves more suffering and produces more good. Just the reassurance of having the option of euthanasia or physician-assisted suicide, even if people do not use it, can provide "psychological insurance" and be beneficial to people. Third, euthanasia and physician-assisted suicide are no different from termination of life-sustaining treatments that are recognized as ethically justified. In both cases, the patient consents to die; in both cases, the physician intends to end the patient's life and takes some action to end the patient's life; and in both cases, the final result is the same: the patient's death. With no difference in the patient's consent, the physician's intention, or the final result, there can be no difference in the ethical justification. Fourth, the supposed slippery slope that would result from permitting euthanasia and physician-assisted suicide is not likely. The idea that permitting euthanasia and physician-assisted suicide would undermine the physician-patient relationship or lead to forced euthanasia is completely speculative and not borne out by the available data.

In its 1997 decisions, the U.S. Supreme Court stated that there is no constitutional right to euthanasia and physician-assisted suicide but that there also is no constitutional prohibition against states legalizing these interventions. Consequently, the legalization of physician-assisted suicide in Oregon and Washington State was constitutional.

Empirical Data

Attitudes and practices related to euthanasia and physician-assisted suicide have been studied extensively. First, surveys indicate that about 60 to 70% of the American and British public support legalizing euthanasia and physician-assisted suicide for terminally ill patients who are suffering intractable pain. However, public support declines significantly for euthanasia and physician-assisted suicide in other circumstances. American and British physicians, however, are much less likely to support euthanasia and physician-assisted suicide, with oncologists, palliative care physicians, and geriatricians among the least supportive. Second, approximately 18 to 25% of American physicians have received requests for euthanasia or physician-assisted suicide; 43 to 63% of oncologists have received requests. Third, multiple studies indicate that less than 5% of American physicians have performed euthanasia or physician-assisted suicide. Among oncologists, 4% have performed euthanasia and 11% have performed physician-assisted suicide during their careers. Fourth, in many cases, the safeguards are violated. One study found that in 54% of euthanasia cases, it was the family who made the request; in 39% of euthanasia and 19% of physician-assisted suicide cases, the patient was depressed; in only half of the cases was the request repeated.

In the Netherlands and Belgium, where euthanasia and physician-assisted suicide are legal, less than 2% of all deaths are by these measures, with 0.4 to 1.8% of all deaths as the result of euthanasia without the patient's consent. In Oregon, about 0.2% of all deaths are by physician-assisted suicide.

Counterintuitively, data indicate that it is not pain that primarily motivates requests for euthanasia or physician-assisted suicide but rather psychological distress, especially depression and hopelessness. Interviews with physicians and with patients with amyotrophic lateral sclerosis, cancer, or infection with human immunodeficiency virus show that pain is not associated with interest in euthanasia or physician-assisted suicide; instead, depression and hopelessness are the strongest predictors of interest. Studies of patients in Australia

and the Netherlands confirm the importance of depression in motivating requests for euthanasia. The desire to avoid dependence and loss of dignity are key motivations.

Finally, data from the Netherlands and the United States suggest that there are significant problems in performing euthanasia and physician-assisted suicide. Dutch researchers reported that physician-assisted suicide causes complications in 7% of cases, and in 15% of cases, the patients did not die, awoke from coma, or vomited up the medication. Ultimately, in nearly 20% of physician-assisted suicide cases, the physician ended up injecting the patient with life-ending medication, converting physician-assisted suicide to euthanasia. These data raise serious questions about how to address complications of physician-assisted suicide when euthanasia is illegal or unacceptable.

Practical Considerations

There is widespread agreement that if euthanasia and physician-assisted suicide are used, they should be considered only after all attempts at physical and psychological palliation have failed. A series of safeguards have been developed and embodied in the Oregon and the Dutch procedures, as follows: (1) the patient must be competent and must request euthanasia or physician-assisted suicide repeatedly and voluntarily; (2) the patient must have pain or other suffering that cannot be relieved by optimal palliative interventions; (3) there should be a waiting period to ensure that the patient's desire for euthanasia or physician-assisted suicide is stable and sincere; and (4) the physician should obtain a second opinion from an independent physician. Oregon and Washington State require patients to be terminally ill, whereas the Netherlands, Belgium, and Switzerland have no such requirement. Although there have been some prosecutions in the United States, there have been no convictions—except for Dr. Kevorkian—when physicians and others have participated in euthanasia and physician-assisted suicide.

FINANCIAL CONFLICTS OF INTEREST

History

Worrying about how payment and fees affect medical decisions is not new. In 1899, a physician reported that more than 60% of surgeons in Chicago were willing to provide a 50% commission to physicians for referring cases. He subsequently argued that in some cases, this fee splitting led to unnecessary surgical procedures. A 1912 study by the American Medical Association confirmed that fee splitting was a common practice. Selling patent medicines and patenting surgical instruments were other forms of financial conflicts of interest thought to discredit physicians a century ago. In the 1990s, the ethics of capitation for physician services and pharmaceutical prescriptions and payments by pharmaceutical and biotechnology companies to clinical researchers raised the issue of financial conflicts of interest.

Definition and Justification

It commonly is argued that physicians have certain primary interests: (1) to promote the well-being of their patients, (2) to advance biomedical research, (3) to educate future physicians, and, more controversially, (4) to promote public health (Table 2-4). Physicians also have other, secondary interests, such as earning income, raising a family, and pursuing avocational interests. These secondary interests are not evil; typically, they are legitimate, even admirable. A conflict of interest occurs when one of these secondary interests compromises pursuit of a primary interest, especially the patient's well-being.

Conflicts of interest are problematic because they can or appear to compromise the integrity of physicians' judgment, compromising the patient's well-being or research integrity. Conflict of interest can induce a physician to do something—perform a procedure, fail to order a test, or distort data—that would not be in a patient's best interest. These conflicts can undermine the trust of patients and the public, not only in an individual physician but also in the entire medical profession. The appearance of conflicts of interest can be damaging because it is difficult for patients and the public "to determine what motives have influenced a professional decision." The focus is on financial conflicts of interest, not because they are worse than other types of conflicts but because they are more pervasive and more easily identified and regulated compared with other conflicts. Since ancient times, the ethical norm on conflicts has been clear: the physician's primary obligation is to patients' well-being, and a physician's personal financial well-being should not compromise this duty.

TABLE 2-4 PRIMARY INTERESTS OF PHYSICIANS

Promotion of the health and well-being of their patients
Advancement of biomedical knowledge through research
Education of future physicians and health care providers
Promotion of the public health

Empirical Data

Financial conflicts are not rare. In Florida, it was estimated that nearly 40% of physicians were involved as owners of freestanding facilities to which they referred patients. Studies in the early 1990s consistently showed that self-referring physicians ordered more services, frequently charged more per service, and referred patients with less established indications. In one study, 4 to 4.5 times more imaging examinations were ordered by self-referring physicians than by physicians who referred patients to radiologists. Similarly, patients referred to joint-venture physical therapy facilities have an average of 16 visits compared with 11 at non–joint-venture facilities. Of great concern, licensed physical therapists at joint-venture facilities spent about 28 minutes per patient per visit compared with 48 minutes at non–joint-venture facilities. There are no comparable data on the influence of capitation on physicians' judgment.

Similarly, multiple studies have shown that interaction with pharmaceutical representatives can lead to prescribing of new drugs, nonrational prescribing, and decreased use of generic drugs by physicians. Industry funding for continuing medical education payment for travel to educational symposia increases prescribing of the sponsor's drug.

Regarding researcher conflicts of interest, the available data suggest that corporate funding does not compromise the design and methodology of clinical research; in fact, commercially funded research may be methodologically more rigorous than government- or foundation-supported research. Conversely, data suggest that financial interests do distort researchers' interpretation of data. The most important impact of financial interests, however, appears to be on dissemination of research studies. Growing evidence suggests the suppression or selective publication of data unfavorable to corporate sponsors but the repeated publication of favorable results.

Practical Considerations

First, financial conflicts of interest are inherent in any profession when the professional earns income from rendering a service. Second, conflicts come in many different forms, from legitimate payment for services rendered to investments in medical laboratories and facilities, drug company dinners and payment for attendance at meetings, payment for enrolling patients in clinical research trials, and consultation with companies.

Third, in considering how to manage conflicts, it is important to note that people are poor judges of their own potential conflicts. Individuals often cannot distinguish the various influences that guide their judgments, do not think of themselves as bad, and do not imagine that payment shapes their judgments. Physicians tend to be defensive about charges of conflicts of interest. In addition, conflicts tend to act insidiously, subtly changing practice patterns so that they then become what appear to be justifiable norms.

Fourth, rules—whether laws, regulations, or professional standards—to regulate conflicts of interest are based on two considerations: (1) the likelihood that payment or other secondary interests would create a conflict and (2) the magnitude of the potential harm if there is compromised judgment. Rules tend to be of three types: (1) disclosure of conflicts, (2) management of conflicts, and (3) outright prohibition. Federal law bans certain types of self-referral of physicians in the Medicare program. The American Medical Association and the Pharmaceutical Research and Manufacturers of America have established joint rules that permit physicians to accept gifts of minimal value but "refuse substantial gifts from drug companies, such as the costs of travel, lodging, or other personal expenses . . . for attending conferences or meetings."

Fifth, although there is much emphasis on disclosure of conflicts, which may be useful in publications, it is unclear whether this is a suitable safeguard in the clinical setting. Disclosure just may make patients worry more. Patients may have no context in which to place the disclosure or to evaluate the physician's clinical recommendation, and patients may have few

other options in selecting a physician or getting care, especially in an acute situation. Furthermore, self-disclosure often is incomplete, even when required.

Finally, some conflicts can be avoided by a physician's own action. Physicians can refuse to engage in personal investments in medical facilities or to accept gifts from pharmaceutical companies at relatively little personal cost. In other circumstances, the conflicts may be institutionalized, and minimizing them can occur only by changing the way organizations structure reimbursement incentives. Capitation encourages physicians to limit medical services, and its potentially adverse effects are likely to be managed by institutional rules rather than by personal decisions.

FUTURE DIRECTIONS

In the near future, as genetics moves from the research to the clinical setting, practicing physicians are likely to encounter issues surrounding genetic testing, counseling, and treatment. The use of genetic tests without the extensive counseling so common in research studies would alter the nature of the bioethical issues. Because these tests have serious implications for the patient and others, scrupulous attention to informed consent must occur. The bioethical issues raised by genetic tests for somatic cell changes, such as tests that occur commonly in cancer diagnosis and risk stratification, are no different from the issues raised with the use of any laboratory or radiographic test.

In some cases, ethics consultation services may be of assistance in resolving bioethical dilemmas, although current data suggest that consultation services are used mainly for problems that arise in individual cases and are not used for more institutional or policy problems.

CARE OF DYING PATIENTS AND THEIR FAMILIES

ROBERT ARNOLD

By 2030, 20% of the U.S. population will be older than 65 years. Owing to successes in public health and medicine, many of these people will live the last years of their lives with chronic medical conditions such as cirrhosis, end-stage kidney disease, heart failure, and dementia. Even human immunodeficiency virus (HIV) and many cancers, once considered terminal, have turned into chronic diseases.

The burden associated with these illnesses is high. Patients report multiple physical and psychological symptoms that lower their quality of life. The economic pressures associated with medical care may adversely affect patients' socioeconomic status and cause family stress. In addition, these chronic illnesses are incurable and often will ultimately contribute to or result in death.

The discipline of palliative care was developed to decrease the burden associated with chronic illness. The recent National Consensus Project defines palliative care as follows:

> *The goal of palliative care is to prevent and relieve suffering and to support the best possible quality of life for patients and their families. Palliative care is operationalized through effective management of pain and other distressing symptoms, while incorporating psychosocial and spiritual care with consideration of family and patient needs, preferences, values, beliefs, and culture .... Palliative care affirms life by supporting the patient and family's goals for the future, including their hopes for cure or life-prolongation, as well as their hopes for peace and dignity throughout the course of illness, the dying process, and death.*

Four points deserve special emphasis. First, palliative care can be delivered at any time during the course of an illness and is often provided concomitantly with disease-focused, life-prolonging therapy. Waiting until a patient is dying to provide palliative care is a serious error. Prognostication is an inexact science. In addition, although most elderly patients with chronic incurable illnesses are in the last 10 years of their lives, they do not consider themselves to be dying. If palliative care is to have an impact on patients' lives, it should be provided earlier in a patient's illness, in tandem with other treatments.

Second, palliative care primarily focuses on the illness's burden rather than treating the illness itself. Because these burdens can be physical, psychological, spiritual, or social, good palliative care requires a multidisciplinary approach.

Third, palliative care takes the family unit as the central focus of care. Treatment plans must be developed for both the patient and the family.

Finally, palliative care recognizes that medical treatments are not uniformly successful and that patients die. At some point in a patient's illness, the treatments may cause more burden than benefit. Palliative care recognizes this reality and starts with a discussion of the patient's goals and the development of an individualized treatment plan.

Many people confuse palliative care with hospice—an understandable confusion because hospices epitomize the palliative care philosophy. The two, however, are different. In the United States, hospice provides palliative care, primarily at home, for patients who have a life expectancy of 6 months or less and who are willing to forgo life-prolonging treatments. However, the requirement that patients must have a life expectancy of less than 6 months limits hospice's availability because this degree of prognostication is difficult to achieve for many diseases. Moreover, doctors and patients often are unwilling to cease potentially life-prolonging treatments until very late in the disease course, and thus, most patients are not enrolled in hospice until a month before death.

Palliative care, both as a philosophy of care and as a subspecialty, now includes training of medical students and residents. Although every physician should have basic knowledge about palliative care, the creation of the new subspecialty of palliative medicine allows for a growing number of physicians capable of helping with difficult patient issues, educating other physicians, and expanding the knowledge base of palliative care.

PALLIATIVE CARE DOMAINS

Palliative care is a holistic discipline with physical, psychological, spiritual, existential, social, and ethical domains. When caring for patients with chronic life-limiting illness, good palliative care requires that the following questions be addressed:

Is the Patient Physically Comfortable?

Across many chronic conditions, patients have a large number of inadequately treated physical symptoms (Table 3-1). The reasons are multifactorial and range from inadequate physician education, to societal beliefs regarding the inevitability of suffering in chronic illness, to public concerns regarding opioids.

The first step to improve symptom management is a thorough assessment. Standardized instruments such as the Brief Pain Inventory (Fig. 3-1) measure both patients' symptoms and their effect on their lives. Use of standardized instruments assures that physicians will identify overlooked or underreported symptoms and, as a result, will enhance the satisfaction of both the patient and family.

The evidence for the treatment of end-stage symptoms continues to improve. Physicians now can use proven therapies to manage pain (Chapter 29), dyspnea (Chapters 50 and 83), and depression (Chapter 404). The use of nonsteroidal anti-inflammatory agents and opioids can result in effective pain management in more than 75% of patients with cancer.■ Advances such as intrathecal pumps and neurolytic blocks are helpful in the remaining 25%. Opioids are effective in patients with unrelieved dyspnea, and oxygen is helpful for short-term relief of hypoxemia.■ Depression can be treated effectively with medications and psychotherapy.■

Is the Patient Psychologically Suffering?

Patients may be physically comfortable but still suffering. Psychological symptoms and syndromes such as depression, delirium, and anxiety are common in patients with life-limiting or chronic illnesses. It may be difficult

TABLE 3-1 APPROACHES TO THE MANAGEMENT OF PHYSICAL AND PSYCHOLOGICAL SYMPTOMS

SYMPTOM	ASSESSMENT	TREATMENT
Pain	How severe is the symptom (as assessed with the use of validated instruments) and how does it interfere with the patient's life? What is the etiology of the pain? Is the pain assumed to be neuropathic or somatic? What has the patient used in the past (calculate previous days' equal analgesic dose)?	Prescribe medications to be administered on a standing or regular basis if pain is frequent. For mild pain: use acetaminophen or a nonsteroidal anti-inflammatory agent (see Table 29-3 in Chapter 29). For moderate pain: titrate short-acting opioids (see Table 29-4 in Chapter 29). For severe pain: rapidly titrate short-acting opioids until pain is relieved or intolerable side effects develop; start long-acting opiates once pain is controlled. Rescue doses: prescribe immediate-release opioids—10% of the 24-hour total opiate every hour (orally) or every 30 minutes (parenterally) as needed. Concomitant analgesics (e.g., corticosteroids, anticonvulsants, tricyclic antidepressants, and bisphosphonates) should be used when applicable (particularly for neuropathic pain). Consider alternative medicine and interventional treatments for pain.
Constipation	Is the patient taking opioids? Does the patient have a fecal impaction?	Prescribe laxatives for all patients on opiates. If ineffective, add drugs from multiple classes (e.g., stimulant, osmotic laxatives, and enemas). Prescribe methylnaltrexone if still constipated.
Shortness of breath	Ask the patient to assess the severity of the shortness of breath. Does the symptom have reversible causes?	Prescribe oxygen to treat hypoxia-induced dyspnea, *but* not if the patient is not hypoxic. Opioids relieve breathlessness without measurable reductions in respiratory rate or oxygen saturation; effective doses are often lower than those used to treat pain. Aerosolized opiates do not work. Fans or cool air may work through a branch of the trigeminal nerve. Consider anxiolytics (e.g., low-dose benzodiazepines) and use reassurance, relaxation, distraction, and massage therapy.
Fatigue	Is the patient too tired to do activities of daily living? Is the fatigue secondary to depression? Is a disease process causing the symptom or is it secondary to reversible causes?	Provide cognitive education about conserving energy use. Treat underlying conditions appropriately.
Nausea	Which mechanism is causing the symptom (e.g., stimulation of the chemoreceptor trigger zone, gastric stimulation, delayed gastric emptying or "squashed stomach" syndrome, bowel obstruction, intracranial processes, or vestibular vertigo)? Is the patient constipated?	Prescribe an agent directed at the underlying cause (Chapter 134). If persistent, give antiemetic around the clock. Multiple agents directed at various receptors or mechanisms may be required.
Anorexia and cachexia	Is a disease process causing the symptom, or is it secondary to other symptoms (e.g., nausea and constipation) that can be treated? Is the patient troubled by the symptom or is the family worried about what not eating means?	A nutritionist may help find foods that are more appetizing (Chapter 220). Provide counseling about the prognostic implications of anorexia (Chapter 226).
Delirium	Is the confusion acute, over hours to days? Does consciousness wax and wane? Are there behavioral disturbances, marked by a reduced clarity in the patient's awareness of his environment, e.g., a problem of attention? Does the patient have disorganized thinking? Does the patient have an altered level of consciousness—either agitated or drowsy? Is there a reversible reason for the delirium? **D:** Drugs (opioids, anticholinergics, sedatives, benzodiazepines, steroids, chemotherapies and immunotherapies, some antibiotics) **E:** Eyes and ears (poor vision and hearing, isolation) **L:** Low-flow states (hypoxia, MI, CHF, COPD, shock) **I:** Infections **R:** Retention (urine/stool), Restraints **I:** Intracranial (CNS metastases, seizures, subdural, CVA, hypertensive encephalopathy) **U:** Underhydration, Undernutrition, Undersleep **M:** Metabolic disorders (sodium, glucose, thyroid, hepatic, deficiencies of vitamin B_{12}, folate, niacin, and thiamine) and toxic (lead, manganese, mercury, alcohol)	Identify underlying causes and manage symptoms (Chapter 27). Recommend behavioral therapies, including avoidance of excess stimulation, frequent reorientation, and reassurance. Ensure presence of family caregivers and explain delirium to them. Prescribe haloperidol, risperidone, or olanzapine.
Depression	Are you feeling down, depressed, or hopeless most of the time over the last 2 weeks? Do you find that little brings you pleasure or joy over the last 2 weeks? (Somatic symptoms are not reliable indicators of depression in this population.)	Recommend supportive psychotherapy, cognitive approaches, behavioral techniques, pharmacologic therapies (see Table 404-5 in Chapter 404), or a combination of these interventions; prescribe psychostimulants for rapid treatment of symptoms (within days) or selective serotonin reuptake inhibitors, which may require 3 to 4 weeks to take effect; tricyclic antidepressants are relatively contraindicated because of their side effects.
Anxiety (applicable also for family members)	Does the patient exhibit restlessness, agitation, insomnia, hyperventilation, tachycardia, or excessive worry? Is the patient depressed? Is there a spiritual or existential concern underlying the anxiety?	Recommend supportive counseling and consider prescribing benzodiazepines.
Spiritual distress	Are you at peace?	Inquire about spiritual support.

DO NOT WRITE ABOVE THIS LINE

Brief Pain Inventory (Short Form)

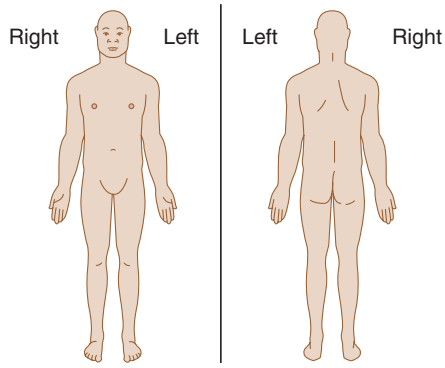
Date: ___/___/___ Time: _____

Name: _____ (Last) _____ (First) _____ (Middle Initial)

1. Throughout our lives, most of us have had pain from time to time (such as minor headaches, sprains, and toothaches). Have you had pain other than these everyday kinds of pain today?

1. Yes 2. No

2. On the diagram, shade in the areas where you feel pain. Put an X on the area that hurts the most.



3. Please rate your pain by circling the one number that best describes your pain at its worst in the last 24 hours.

0	1	2	3	4	5	6	7	8	9	10
No pain										Pain as bad as you can imagine

4. Please rate your pain by circling the one number that best describes your pain at its least in the last 24 hours.

0	1	2	3	4	5	6	7	8	9	10
No pain										Pain as bad as you can imagine

5. Please rate your pain by circling the one number that best describes your pain on the average.

0	1	2	3	4	5	6	7	8	9	10
No pain										Pain as bad as you can imagine

6. Please rate your pain by circling the one number that tells how much pain you have right now.

0	1	2	3	4	5	6	7	8	9	10
No pain										Pain as bad as you can imagine

to determine whether increased morbidity and mortality are caused by the illness's physical effects or by the psychological effects of depression and anxiety on energy, appetite, or sleep. Screening questions focusing on mood (e.g., "Have you felt down, depressed, and hopeless most of the time for the last 2 weeks?") and anhedonism (e.g., "Have you found little brings you pleasure or joy in the last 2 weeks?") have been shown to help in diagnosing depression in this population.

For patients and families facing mortality, existential and spiritual concerns are common. Progressive illness often raises questions of love, legacy, loss, and meaning. A physician's role is not to answer these questions or to provide reassurance, but rather to understand the patient's concerns, how the patient is coping, and what resources might be of help. Spirituality often is a source of comfort, and physicians can screen regarding a patient's beliefs using a brief instrument such as the FICA spiritual assessment tool (Table 3-2). A single

7. What treatments or medications are you receiving for your pain?

_____

8. In the last 24 hours, how much relief have pain treatments or medications provided? Please circle the one percentage that most shows how much relief you have received.

0%	10%	20%	30%	40%	50%	60%	70%	80%	90%	100%
No pain										Complete relief

9. Circle one number that describes how, during the past 24 hours, pain has interfered with your:

A. General Activity

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

B. Mood

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

C. Walking Ability

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

D. Normal Work (includes both work outside the home and housework)

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

E. Relations with Other People

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

F. Sleep

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

G. Enjoyment of Life

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

screening question, such as "Are you at peace?," may identify patients who are in spiritual distress and facilitate referrals to hospital chaplains.

Is the Family Suffering?

Families are an important source of support for most patients. Families provide informal care-giving, often at the expense of their own physical, economic, and psychological health. Good palliative care requires an understanding of how the family is coping and a search for ways to provide family members with the social or clinical resources they need to improve their well-being. Comprehensive and individually targeted interventions can reduce caregivers' burdens, although the absolute benefits are relatively small.

Because patients in palliative care often die, the palliative care team must address bereavement. A letter of condolence or a follow-up phone call to the next of kin after a patient's death is respectful and offers the opportunity to clarify questions about the patient's care. Some family members suffer from complicated grief—a recently described syndrome associated with separation and traumatic distress, with symptoms persisting for more than 6 months. Primary care physicians, who have ongoing relationships with the loved one, and hospices, which provide bereavement services for a year after the patient's death, have the opportunity to assess whether the grief symptoms persist or worsen.

Is the Patient's Care Consistent with the Patient's Goals?

The sine qua non for palliative care is ensuring that the treatment plan is consistent with the patient's values. Most elderly, seriously ill patients are not focused on living as long as possible. Instead, they want to maintain a sense

TABLE 3-2 FICA SPIRITUAL ASSESSMENT TOOL

F	What is your **faith**/religion? Do you consider yourself a religious or spiritual person? What do you believe in that gives meaning/importance to life?
I	**Importance** and **influence** of faith. Is your faith/religion important to you? How do your beliefs influence how you take care of yourself? What are your most important hopes? What role do your beliefs play in regaining your health? What makes life most worth living for you? How might your disease affect this?
C	Are you part of a religious or spiritual **community**? Is this of support to you, and how? Is there a person you really love or is very important to you? How is your family handling your illness? What are their reactions/expectations?
A	How would you like me to **address** these issues in your health care? What might be left undone if you were to die today? Given the severity or chronicity of your illness, what is most important for you to achieve? Would you like me to talk to someone about religious/spiritual matters?

From Puchalski C, Romer A. Taking a spiritual history. *J Palliat Med*. 2000;3:129-137.

of control, relieve their symptoms, improve their quality of life, avoid being a burden on their families, and have a closer relationship with their loved ones.

Ensuring that treatment is consistent with a patient's goals requires good communication skills (Table 3-3). The approaches to giving bad news, discussing goals of care, and talking about forgoing life-sustaining treatment have similar structures (Fig. 3-2). First, the patient needs to understand the basic facts about the diagnosis, possible treatments, and prognosis. The communication skill that helps physicians communicate information is *Ask-Tell-Ask*—exploring what the patient knows or wants to know, then explaining or answering questions, and then providing an opportunity for the patient to ask more. In the hospital, where discontinuity of care is common and misunderstandings frequent, it is important to determine what the patient knows before providing information so as to keep everyone well coordinated. When giving bad news, knowing what the patient knows allows the physician to anticipate the patient's reaction. Finally, information must be titrated based on the patient's preferences. Although most patients want to hear everything about their disease, a minority do not. There is no foolproof way to ascertain what any patient wants to know other than by asking.

When giving patients information, it is important to give small pieces of information, not use jargon, and check the patient's understanding. Giving information is like dosing a medication: one gives information, checks understanding, and then gives more information based on what the patient has heard.

After ensuring that the doctor and the patient have a shared understanding of the medical facts, the physician should engage in an open-ended conversation about the patient's goals as the disease progresses. This strategy requires that the patient be asked about both hopes and fears. One might ask: "What makes life worth living for you?" "If your time is limited, what are the things that are most important to achieve?" "What are your biggest fears or concerns?" "What would you consider to be a fate worse than death?" The clinician can use an understanding of these goals to make recommendations about which treatments to provide and which treatments would not be helpful. As a result, early palliative care can improve quality of life, mood, and even survival.■

Physicians find talking about prognosis particularly difficult for two reasons: first, it is hard to foretell the future accurately; and second, they fear this information will "take away patients' hope." Thus, they often avoid talking to patients about these issues unless specifically asked. Although some patients do not want to hear prognostic information, for many patients, this information helps them plan their lives. Given that one cannot guess how much information to provide, a physician can start these conversations by asking, "Are you the kind of person who wants to hear about what might happen in the future with your illness or would you rather take it day by day?" If the patient requests the latter, the physician can follow up by asking if there is someone else with whom he or she can talk about the prognosis. Second, before giving prognostic information, it is useful to inquire about the patient's concerns in order to provide information in the most useful manner. Finally, it is appropriate when discussing prognostic information to acknowledge uncertainty: "The course of this cancer can be quite unpredictable, and physicians don't have a crystal ball. I think you should be aware of the possibility that your health may deteriorate quickly, and you should plan accordingly. We probably are dealing with weeks to months, although some patients do better, and some do worse. Over time, the course may become clearer, and if you wish, I may be able to be a little more precise about what we are facing."

TABLE 3-3 CORE COMMUNICATION SKILLS

RECOMMENDED SKILL	EXAMPLE
A. IDENTIFYING CONCERNS AND RECOGNIZING CUES	
Elicit Concerns	
Open-ended questions	"Is there anything you wanted to talk to me about today?"
Active listening	Allowing patient to speak without interruption; allowing pauses to encourage patient to speak
Recognize Cues	
Informational concerns	Patient: "I'm not sure about the treatment options"
Emotional concerns	Patient: "I'm worried about that"
B. RESPONDING TO INFORMATIONAL CONCERNS	
"Ask-tell-ask"	Topic: communicating information about cancer stage
Ask	"Have any of the other doctors talked about what stage this cancer is?"
Tell	"That's right, this is a stage IV cancer, which is also called metastatic cancer...."
Ask	"Do you have questions about the staging?"
C. RESPONDING TO EMOTIONAL CONCERNS	
Nonverbal Empathy: S-O-L-E-R	
S	Face the patient **S**quarely
O	Adopt an **O**pen body posture
L	**L**ean toward the patient
E	Use **E**ye contact
R	Maintain a **R**elaxed body posture
Verbal Empathy: N-U-R-S-E	
N	**N**ame the emotion: "You seem worried"
U	**U**nderstand the emotion: "I see why you are concerned about this"
R	**R**espect the emotion: "You have shown a lot of strength"
S	**S**upport the patient: "I want you to know that I will still be your doctor whether you have chemotherapy or not"
E	**E**xplore the emotion: "Tell me more about what is worrying you"

From Back AL, Arnold RM, Tulsky JA. *Discussing Prognosis*. Alexandria, VA: American Society of Clinical Oncology; 2008.

The physician must discuss these topics in an empathic way. Palliative care conversations are as much about emotions as facts. Talking about disease progression or death may elicit negative emotions such as anxiety, sadness, or frustration. These emotions decrease a patient's quality of life and interfere with the ability to hear factual information. Empathic responses strengthen the patient-physician relationship, increase the patient's satisfaction, and make the patient more likely to disclose other concerns. The first step is recognizing when the patient is expressing emotions. Once the physician recognizes the emotion being expressed, he or she can respond empathically.

It is also important for physicians to recognize their own emotional reactions to these conversations. The physician's emotional reactions color impressions of the patient's prognosis, thereby making it hard to listen to the patient, and may influence the physician to hedge bad news. The physician should become aware of her or his own emotional reactions to ensure that the conversation focuses on the patient rather than the health care provider's needs.

In addition to good communication skills, palliative care requires a basic knowledge of medical ethics and the law. For example, patients have the moral and legal right to refuse any treatment, even if refusal results in their death. There is no legal difference between withholding and withdrawing life-sustaining treatment. When confronted with areas of ambiguity, the physician should know how to obtain either a palliative care or ethics consultation.

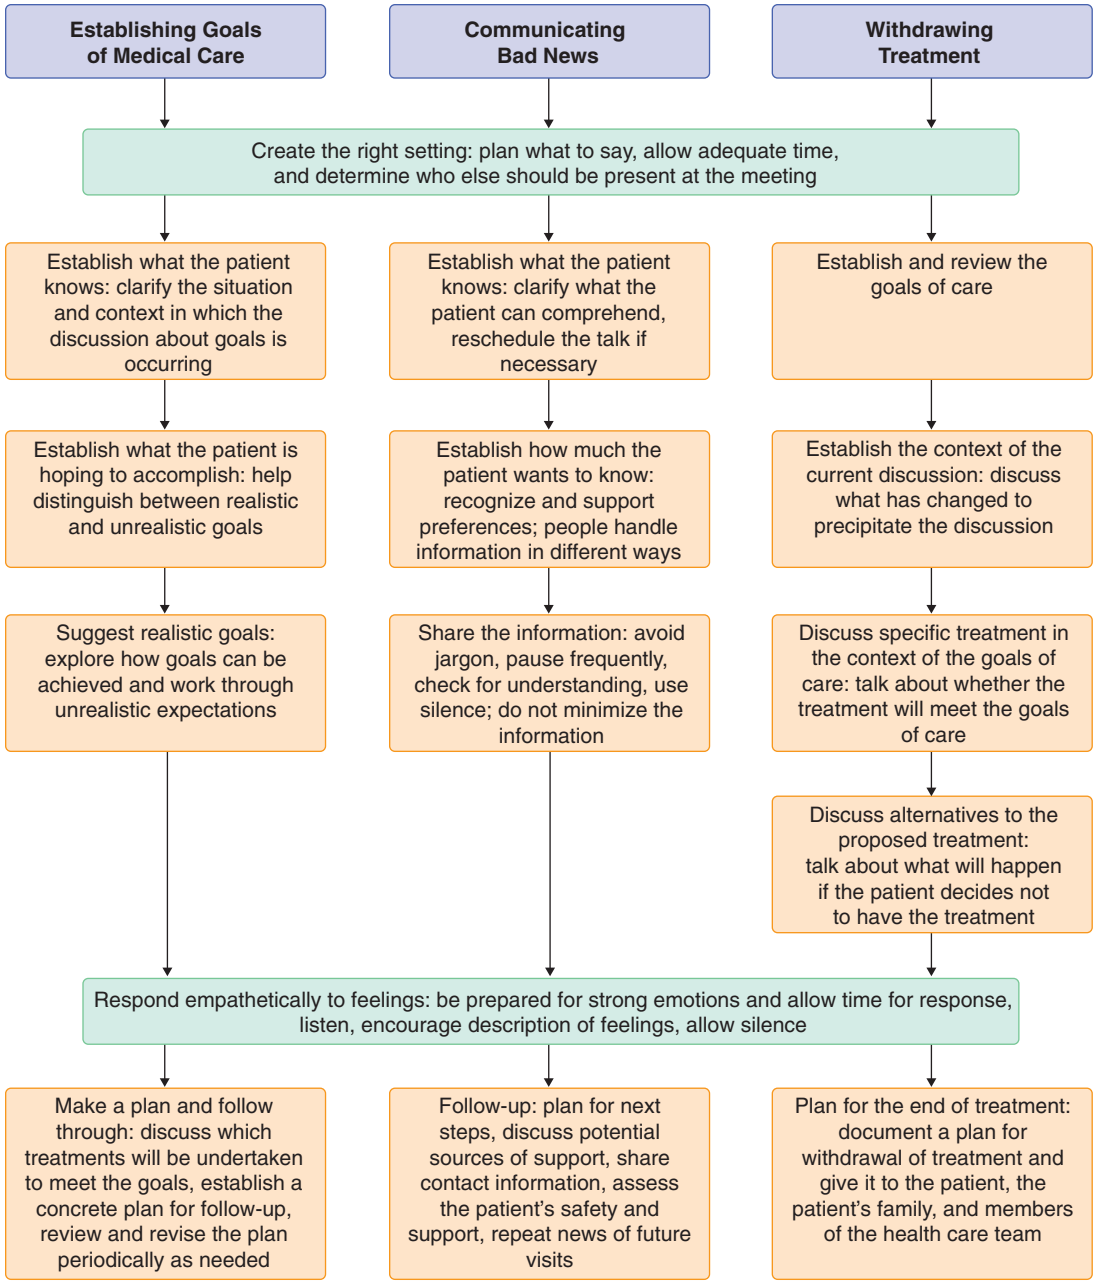

FIGURE 3-2. A model for discussing different palliative care topics. Protocols for Communicating with Patients about Major Topics in Palliative Care. (Adapted from the EPEC Project: Education on Palliative and End-of-Life Care. Cited in Morrison, RS, Meier DE. Palliative care. *N Engl J Med.* 2004; 350:2582-2590; accessed January 4, 2010 from http://www.epec.net.)

During the past 10 years, there has been a societal push to encourage patients to designate health care proxies and to create advance care planning documents, typified by the use of living wills. These documents are meant to protect patients against unwanted treatments and to ensure that as they are dying, their wishes are followed. Unfortunately, there are few empirical data showing that these documents actually change practice. Still, discussions of the documents with health professionals and family members generally provoke important conversations about end-of-life care decisions and may help assuage the family in that they are respecting their loved one's wishes.

Is the Patient Going to Die in the Location of Choice?

Most patients say that they want to die at home. Unfortunately, most patients die in institutions—either hospitals or nursing homes. Good palliative care requires establishing a regular system of communication to minimize transitional errors. A social worker who knows about community resources is important in the development of a dispositional plan that respects the patient's goals.

Hospice programs are an important way to allow patients to die at home. In the United States, *hospice* refers to a specific, government-regulated form of end-of-life care, available under Medicare since 1982 but subsequently adopted by Medicaid and many other third-party insurers. Hospice care typically is given at home, a nursing home, or specialized acute care unit. Care is provided by an interdisciplinary team, which usually includes a physician, nurse, social worker, chaplain, volunteers, bereavement coordinator, and home health aides, all of whom collaborate with the primary care physician, patient, and family. Bereavement services are offered to the family for a year after the death.

Hospices are paid on a per diem rate and are required to cover all the costs related to the patient's life-limiting illness. Because of this and the fact their focus is on comfort rather than life prolongation, many hospices will not cover expensive treatments such as inotropic agents in heart failure or chemotherapy in cancer, even if they have a palliative effect. This may be one of the reasons doctors are hesitant to refer patients until very late in a patient's course, and patients and families equate hospice with dying. Many hospices are experimenting with different service models in an attempt to enroll patients earlier in the course of their illness and increase access to their services.

From Holtby S, Zahnd E, Chia YJ, et al. *Health of California's Adults, Adolescents, and Children: Findings from CHIS 2005 and CHIS 2003*. Los Angeles: UCLA Center for Health Policy Research; 2008.

The 2000 U.S. Census counted more than 36 million Americans of African descent (13% of the population), nearly 12 million Asians (4% of the population), more than 4 million American Indians and Alaska Natives, and almost 1 million Native Hawaiians and other Pacific Islanders. In addition, more than 35 million Americans were of Hispanic or Latino descent (13% of the population). More than one tenth (11%) of the total population, 69% of Asians, and 40% of Latinos were foreign born. Residents of the United States now speak more than 300 languages, and 47 million speak a language other than English at home. In 2000, two fifths of Asians (40%) and Hispanics (41%) had limited English proficiency (i.e., did not speak English well or fluently), and the proportions were much higher among some Asian subgroups.

During the past two decades, a large body of literature has documented substantial disparities in health status, some based on socioeconomic status (Chapter 5), but many based on race, ethnicity, or other characteristics. For example, black men have a substantially higher age-adjusted prostate cancer incidence rate than do white men (240 per 100,000 versus 153 per 100,000). Mexican Americans and American Indians are more than twice as likely as non-Latino whites of a similar age to have diabetes. Compared with the general population, chronic hepatitis B infection is 25 to 75 times more common among Samoans and among immigrants from Cambodia, Laos, and Vietnam. Studies have documented high rates of suicidal behavior among gays and lesbians compared with heterosexuals. A major goal of Healthy People 2010 was to eliminate health differences among population subgroups for preventable and treatable conditions such as cancer, cardiovascular disease, diabetes, human immunodeficiency virus infection, and acquired immunodeficiency syndrome, among others.

Culture can be defined as a shared system of values, beliefs, and patterns of behavior, and it is not simply defined by race and ethnicity. Culture can also be shaped by factors such as country and region of origin, acculturation, language, religion, and sexual orientation. For instance, the black population of the northeastern United States includes individuals who moved from southern states decades ago as well as recent immigrants from Ethiopia. As the United States population becomes increasingly diverse and as pronounced differences in health status continue to be documented, consideration of the cultural context of medicine is becoming a national priority.

DISPARITIES IN HEALTH CARE ACCESS AND QUALITY

Components of health care access include the ability to get into the health care system as well as to obtain appropriate care once in the system. The availability of health care providers who meet an individual patient's needs is another key component of access to care. Quality care is based on scientific evidence (i.e., is effective), avoids injury to the patient (i.e., is safe), minimizes harmful delays (i.e., is timely), is responsive to the individual patient's needs (i.e., is patient centered), does not vary because of personal characteristics (i.e., is equitable), and avoids waste (i.e., is efficient) (Chapter 11).

Access and Communication

Racial and ethnic minority groups, particularly Latinos, are disproportionately represented among those with health care access problems. The proportions of Latinos who lack health insurance and have no regular source of medical care are more than twice the proportions among non-Latino whites (Table 4-1). Latinos are significantly more likely to report problems in obtaining health care for illness or injury, as well as referrals for specialist care, than are non-Latino whites, even after differences in education, income, and insurance coverage are taken into account. Black heterosexual women have significantly higher levels of health insurance coverage than do black lesbian or bisexual women.

Communication between patients and physicians is more of a problem among members of racial and ethnic minority groups than among whites. In one survey, 33% of Latinos, 27% of Asians, 23% of blacks, and 16% of whites reported one or more of the following problems with communication: the doctor did not listen to everything they said, they did not fully understand the doctor, or they had questions that they did not ask during the visit. In addition, Latinos who spoke Spanish as their primary language (43%) were more likely to have one or more communication problems than were those who spoke English as their primary language (26%).

Blacks (23%) and Latinos (26%) are far less likely than whites (82%) to have regular physicians of their own race and ethnicity. Research has shown that racial concordance between physicians and patients can improve the processes and outcomes of care. For instance, patients in race-concordant relationships with their physician rate his or her decision-making style as significantly more participatory and inclusive than do patients in race-discordant relationships. Furthermore, race-concordant office visits last significantly longer than do race-discordant visits.

Quality of Health Care

National surveys confirm population-level disparities in the quality of both preventive care and the management of chronic disease. American Indians/Alaska Natives and Latinos aged 50 years and older are far less likely to receive interval screening for colorectal cancer (Chapter 199) than are members of other racial/ethnic groups (Table 4-2). Compared with white diabetic adults, black and Latino adults with diabetes are more than 30% less likely to receive recommended preventive and screening services (Chapter 236) and are still less likely to receive them after adjustment for insurance coverage.

Racial and ethnic disparities exist in such specific clinical situations as the prescription of analgesia for pain control (blacks receive less pain medication than whites for extremity fractures), the surgical treatment of cancer (blacks are less likely than whites to receive potentially curative surgery for stage I or stage II non–small cell lung cancer), and the management of end-stage renal disease (blacks are less likely to be entered on the transplant list than are whites). Moreover, disparities in the quality of care are consistently found even when variations in such factors as insurance status, income, age, and comorbid conditions are taken into account.

Disparities in health care quality exist even in systems that are generally believed to provide equal access. For example, in Veterans Health Administration facilities, black patients who were ideal candidates to receive thrombolytic therapy (Chapter 73) on arrival were less likely to receive it than comparable white patients. Black patients were also significantly less likely to have coronary artery bypass graft surgery during their index hospitalization or within 90 days after a myocardial infarction even after adjustment for clinical characteristics and differences in patients' preferences. Similarly, of Medicare-managed care plans, black patients were less likely than white patients to receive diabetic retinal examination, post-infarction β-blockers, and post-hospitalization follow-up for mental illness after adjustment for clinical characteristics and for clustering within health plans.

TABLE 4-2 COLORECTAL CANCER SCREENING LEVELS AMONG INDIVIDUALS AGED 50 YEARS AND OLDER BY RACE/ETHNICITY—UNITED STATES, 2006

RACE/ETHNICITY	FOBT LAST YEAR OR LOWER ENDOSCOPY LAST 10 YEARS % (95% CI)
White	62.6 (62.1-63.0)
Black	59.0 (57.3-60.6)
American Indian/Alaska Native	48.4 (43.5-53.2)
Asian American/Pacific Islander	55.9 (51.0-60.7)
Latino	47.2 (44.5-49.9)

CULTURAL COMPETENCE IN HEALTH CARE

Health disparities can be reduced or perhaps even eliminated by maintaining culturally competent health care systems. Cultural competence may be defined as a set of congruent attitudes, behaviors, and policies that come together both among professionals and within systems to enable effective work in cross-cultural situations (Fig. 4-1). Ongoing efforts to improve cultural competence in the U.S. health care system target organizational, structural, and clinical barriers. These initiatives aim to close gaps in health status, to decrease differences in the quality of care, to enhance patients' satisfaction, and to increase patients' trust.

Organizational Barriers and Interventions

Racial and ethnic minority physicians are more likely than their white colleagues to work in medically underserved communities. Moreover, they have a better understanding of barriers to health care (such as office hours that do not match community work patterns, bureaucratic intake processes that create fear of deportation among the undocumented, and long waiting times to get an appointment and, after arrival, to keep an appointment). Finally, minority physicians bring a nuanced awareness of the needs of diverse groups of patients and share it through the critical avenues of role modeling and teaching. However, only 6% of practicing physicians are black, Native American, or Latino, and only 15% of medical school applicants are from one of these groups.

Most (approximately two thirds) patients who receive care at federally funded community health centers in medically underserved areas are members of racial and ethnic minority groups. Further, the proportion of community health center patients who have limited English proficiency is 30% and has grown rapidly since 2000. The community health center model has proved effective not only in increasing access to care but also in improving continuity of care and health outcomes. For example, one study found that medically underserved communities with federally qualifying community health centers had 5.8 fewer preventable hospitalizations per 1000 population over 3 years than did similar communities without health centers. Consequently, ongoing efforts to increase the capacity of community health centers are likely to help reduce health disparities.

Structural Barriers and Interventions

The Department of Health and Human Services has created standards on culturally and linguistically appropriate interpreter services to guide

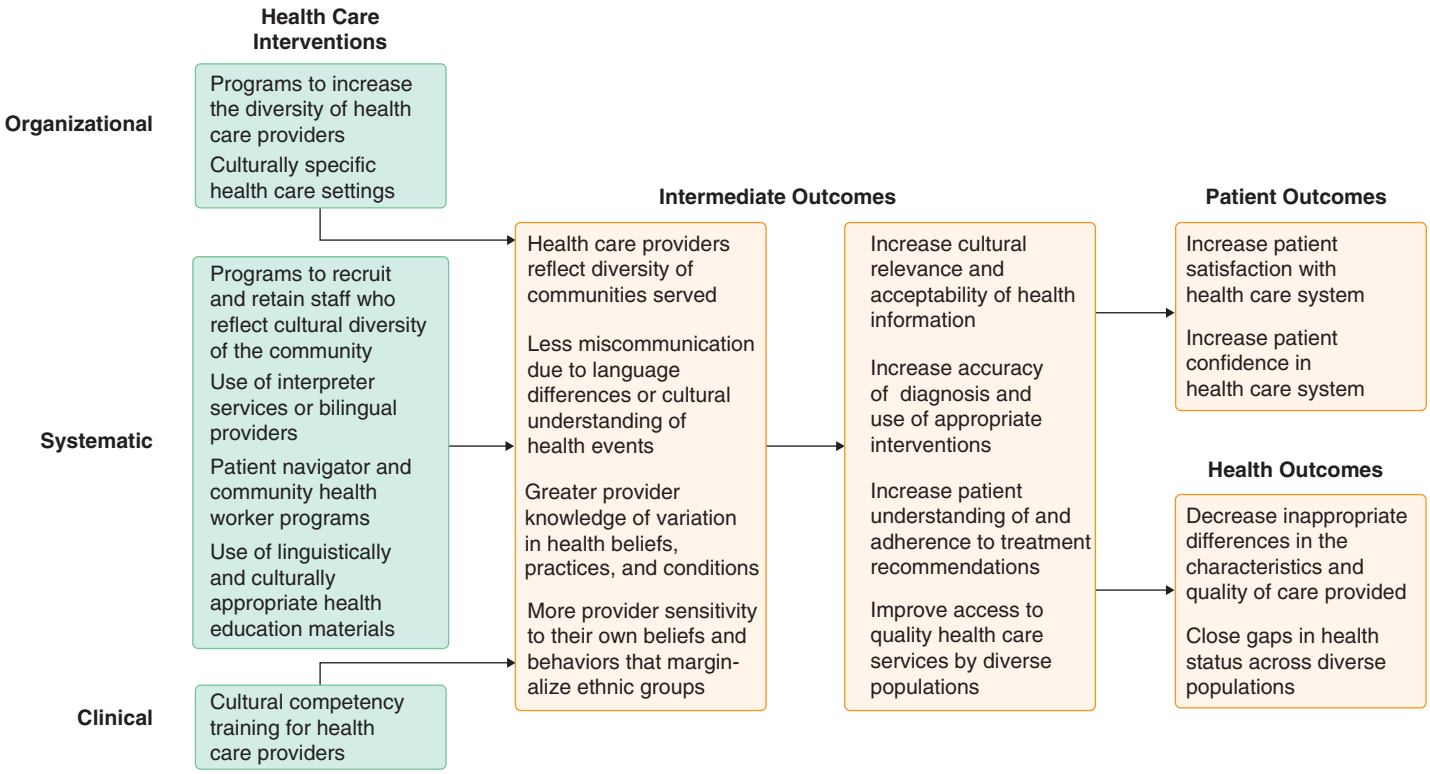

FIGURE 4-1. Analytic framework for evaluating the effectiveness of health care interventions to increase cultural competence. (From Anderson LM, Scrimshaw SC, Fullilove MT, et al, for the Task Force on Community Preventive Services. Culturally competent healthcare systems: a systemic review. *Am J Prev Med.* 2003;24[Suppl]:68-79).

providers. However, interpreter services often remain ad hoc, with family members and untrained nonclinical employees acting as interpreters. Use of ad hoc services has potentially negative clinical consequences, including breach of the patient's confidentiality and inaccurate communication. One major obstacle to the implementation of professional interpreter programs is a lack of reimbursement; Medicare and most private insurers do not pay for interpretation and related services (such as translation or telephone language lines), and only a few states currently pay for interpretation under Medicaid.

Accumulating evidence suggests that trained professional interpreters and bilingual providers can have a positive impact on the satisfaction of patients and quality of care among individuals with limited English proficiency. For example, in a health maintenance organization, the introduction of professional interpreter services for Portuguese- and Spanish-speaking patients increased their use of recommended preventive services, office visits, and number of prescriptions written and filled.

Assistance with "navigation" represents one promising model to enable racial and ethnic minority patients to move through the health system effectively and to be actively involved in decision making about their medical care. Navigator programs rely on personal guides to shepherd disadvantaged patients with chronic diseases into standard care. Guides help patients and their families navigate the treatment process, steering them around obstacles that may limit their access to quality care. For example, guides (who may be nurses, social workers, or volunteers who are familiar with the health care system) help patients choose doctors and assess treatment options. Currently, three major navigation programs (the National Cancer Institute, American Cancer Society, and Center for Medicare and Medicaid Services) are under way to address the needs of medically underserved cancer patients.

Community health workers are increasingly being used in attempts to close the gap in health care among various racial and ethnic minority populations. In general, community health workers live locally and share the language and culture of the population of patients served. Lay community health workers have several core functions; they provide cultural mediation between communities and the health care system, provide culturally appropriate and accessible health education and information, help people obtain the medical services they need, provide informal counseling and social support, and advocate for individuals within the health care system. The largest system formally to use the skills of community health workers is the Indian Health Service, which currently has about 1400 community health representatives who work with tribally managed or Indian Health Service programs in more than 550 American Indian/Alaska Native nations.

Evidence for the effectiveness of community health workers is provided by the breast and cervical cancer screening literature. For example, Vietnamese American women randomized to receive lay health worker group education are significantly more likely to obtain Papanicolaou tests than are women who do not.[1,2]

Clinical Barriers and Interventions

Patients who are members of racial and ethnic minority groups often have an understanding of health and disease (i.e., explanatory model) that differs from that of the general population. For example, many Vietnamese people believe that disease is caused by an imbalance of the humoral forces of yin and yang. When ill, they commonly use Chinese herbal medicine as well as indigenous folk practices known as Southern medicine in an effort to restore the balance of humoral forces. In addition, Vietnamese patients may think that Western medicine is too strong and will upset the internal balance. Consequently, a hypertensive patient, for example, may use Chinese herbal medicines (Chapter 38) instead of prescribed antihypertensive medication. Alternatively, the patient may take a lower dose of medication than prescribed by his or her physician.

Cultural competency training for health care providers generally includes some balance of cross-cultural knowledge and communication skills, taught while avoiding stereotypes. Examples include the effect of prejudice on gays and lesbians and how this prejudice shapes their interactions with the health care system, and common spiritual practices that might interfere with prescribed therapies (such as Ramadan fasting practices, when observed by diabetic Muslim patients). Communication skills that can be addressed in cultural competence training include approaches to eliciting patients' explanatory models and use of traditional treatments as well as methods for negotiating different styles of communication and levels of family participation in decision making. Overall, there is good evidence that cultural competency training improves the attitudes and skills of health professionals as well as patient satisfaction, but less evidence that it improves clinical outcomes.[3]

Training in cultural diversity has recently become part of medical school curricula, often by "weaving" multiculturalism into the curriculum rather than teaching it as a separate course. Program components may include home visits that allow students to hear patients' stories of illness and treatment (and learn about patient-centered care) as well as discussions of clinical cases that allow students to explore issues related to health disparities, health care access, and unequal treatment.

SUMMARY

The average life expectancy of Americans increased by more than 30 years between 1900 and 2000. However, some groups have not fully benefited from the medical and public health achievements of the last century. Although there are demonstrated correlations between racial and ethnic background and socioeconomic status (Chapter 5), poverty alone cannot explain all the gaps in health and health care that exist between minorities and whites. Although the disparities were first documented in blacks in the United States, a growing body of evidence indicates that Latinos and other racial/ethnic minority groups, as well as gays, lesbians, and bisexuals, also experience significant problems with health care access and quality, especially when their English is not proficient.

Efforts to improve cultural competence in health care, whether they are used alone or in conjunction with socioeconomic initiatives (Chapter 5), are likely to play a significant role in reducing health disparities across population subgroups. The dissemination of successful interventions through linkages with payers, policymakers, provider groups, community organizations, and the media will be critical.

SOCIOECONOMIC ISSUES IN MEDICINE

STEVEN A. SCHROEDER

All nations—rich and poor—struggle with how to improve the health of the public, obtain the most value from medical services, and restrain rising health care expenditures. Many developed countries also wrestle with the paradox that their citizens have never been so healthy or so unhappy with their medical care. Despite the reality that only 10% of premature deaths result from inadequate medical care, the bulk of professional and political attention focuses on how to obtain and pay for state-of-the-art medical care. By comparison, 40% of premature deaths stem from unhealthy behaviors—including smoking (about 44%; Chapter 31); excessive or unwise drinking (about 11%; Chapter 32), obesity and insufficient physical activity (about 15% but estimated to rise substantially in the years to come; Chapters 15 and 227), illicit drug use (about 2%; Chapter 33), and imprudent sexual behavior (about 3%; Chapter 293) (E-Fig. 5-1). Genetics (Chapter 39) account for an additional 30%; social factors—discussed next—account for 15%, and environmental factors (Chapter 18) account for 5%. Of the major behavioral causes of premature deaths (Fig. 5-1), tobacco use (Chapter 31) is by far the

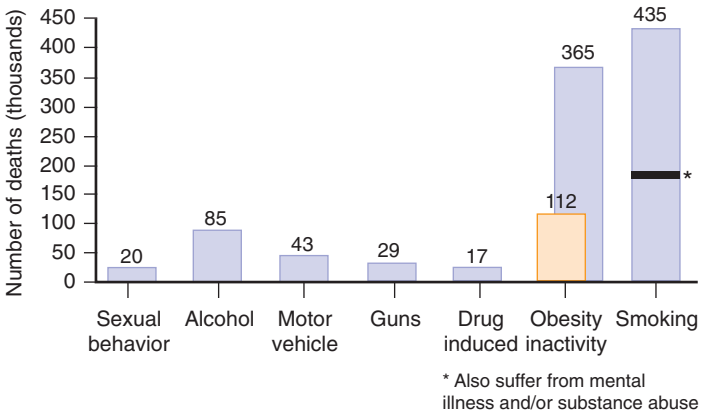

FIGURE 5-1. Number of U.S. deaths from behavioral causes. (Data from Mokdad AH, Marks JS, Stroup DF, Gerberding JL. Actual causes of death in the United States, 2000. *JAMA.* 2004;291:1238-1245; Mokdad AH, Marks JS, Stroup DF, Gerberding JL. FIGURE 5-3. Age-adjusted prevalence of cigarette smoking in 2007, among persons 25 years of age or older, according to educational level. GED = General Education Development test. (From Centers for Disease Control and Prevention. Cigarette smoking among adults—United States, 2007. *MMWR Morb Mortal Wkly Rep.* 2008;57:1221-1226.)

most important, although recent increases in obesity (Chapter 227) and physical inactivity (Chapter 15) are also alarming.

SOCIAL STATUS INFLUENCES HEALTH

Socioeconomic status, or class, is a composite of many different factors, including income, net wealth, education, occupation, and neighborhood. In general, people in lower classes are less healthy and die earlier than people at higher socioeconomic levels, a pattern that holds true in a stepwise fashion from the poorest to the richest. In the United States, the association between health and class is usually discussed in terms of racial and ethnic disparities; but in fact, race and class are independently associated with health status, and it can be argued that class is the more important factor. For example, U.S. racial disparities in adult smoking prevalence are relatively small among whites, blacks, and Hispanic Americans (Fig. 5-2), whereas there are huge differences among smoking rates by educational level (Fig. 5-3). U.S. physicians have reduced their smoking prevalence to a record low of only 1%.

In part, the relationship between class and health is mediated by the higher rates of unhealthy behaviors among the poor, such as the inverse relationship between educational attainment and cigarette smoking, but unhealthy behaviors do not fully explain the poor health of those in the lower socioeconomic classes. Even when behavior is held constant, people in lower socioeconomic classes are much more likely to die prematurely than are people of higher classes. Of interest is that first-generation immigrants appear to be more protected from the adverse health consequences of low socioeconomic status than are subsequent generations.

It is unclear which of the components of class—education, wealth (either absolute wealth or the extent of the gap between rich and poor), occupation, or neighborhood—makes the greatest impact on a person's health. Most likely, it is a combination of all of them. For example, the constant stress of a lower class existence—lack of control over one's life circumstances, social isolation, and the anxiety derived from the feeling of having low status—is linked to poor health. This stress may trigger a variety of neuroendocrinologic responses that are useful for short-term adaptation and bring long-term adverse health consequences.

What can clinicians do with this knowledge? Clearly, it is difficult to write prescriptions for more income or for better schooling or neighborhoods or jobs, but physicians can encourage healthy behavior. At key times of transition, such as during discharge planning for hospitalized patients, clinicians should be attentive to social circumstances. For patients who are likely to be socially isolated, clinicians should encourage or arrange interactions with family, neighbors, religious organizations, or community agencies to improve the likelihood of optimal outcomes. In addition, physicians should seek to identify and to eliminate any aspects of racism in health care institutions. Finally, in their role as social advocates, physicians can promote such goals as safe neighborhoods, improved schools, and equitable taxation policies.

ECONOMIC ISSUES IN MEDICAL CARE

Medical care today is on a collision course. On the one hand, an ever-expanding science base continuously generates new technologies and drugs that promise a longer and healthier life. Add a public eager to obtain the latest breakthroughs touted in the media and over the Internet, plus a well-stocked medical industry eager to meet that demand, and it is easy to understand why expenditures continue to soar. On the other hand, payers for medical care—health insurance companies, government (federal, state, and local), and employers—increasingly bridle at medical care costs.

The United States continues to lead the world in health care expenditures (Fig. 5-4). In 2008, it spent about $2.4 trillion, amounting to 17% of its gross domestic product. It is projected that expenditures will continue to rise, exceeding 20% by 2014. Most policy analysts contend that this rate of increase in medical care expenditures is unsustainable, but the same has been said for many years. Few other countries have double-digit health care expenditures, and none comes close to 15% (see Fig. 5-4). A potent combination of supply and demand factors explains why the United States spends so much. On the supply side, it far exceeds other countries in the availability and use of expensive diagnostic technologies, such as magnetic resonance imaging and computed tomography (E-Fig. 5-2). For example, the United States has four times as many magnetic resonance imaging machines per capita as does Canada. Similar patterns exist for therapeutic technologies, whether coronary angioplasty, cancer chemotherapy, or joint prostheses. The differences are especially dramatic in older patients. For example, in the 65- to 69-year age group, the United States performed 1.95 more carotid endarterectomy procedures per capita than did Canada; but above the age of 80 years, the ratio was 8.7.

Other supply factors that drive high medical expenditures in the United States include a fee-for-service payment system that compensates physicians much more for using expensive technologies than when they do not; a medical professional work force that earns much higher incomes relative to the population than in other nations and that emphasizes specialist rather than generalist practice; accelerated development of new and costly medications that are directly marketed to consumers; much higher administrative costs; higher rates of fraud and abuse; and a high rate of defensive medicine in response to pervasive fears about medical malpractice suits. Supply factors that do not appear to be unique to the United States are the number of physicians or hospitals. Many other developed countries have a much larger

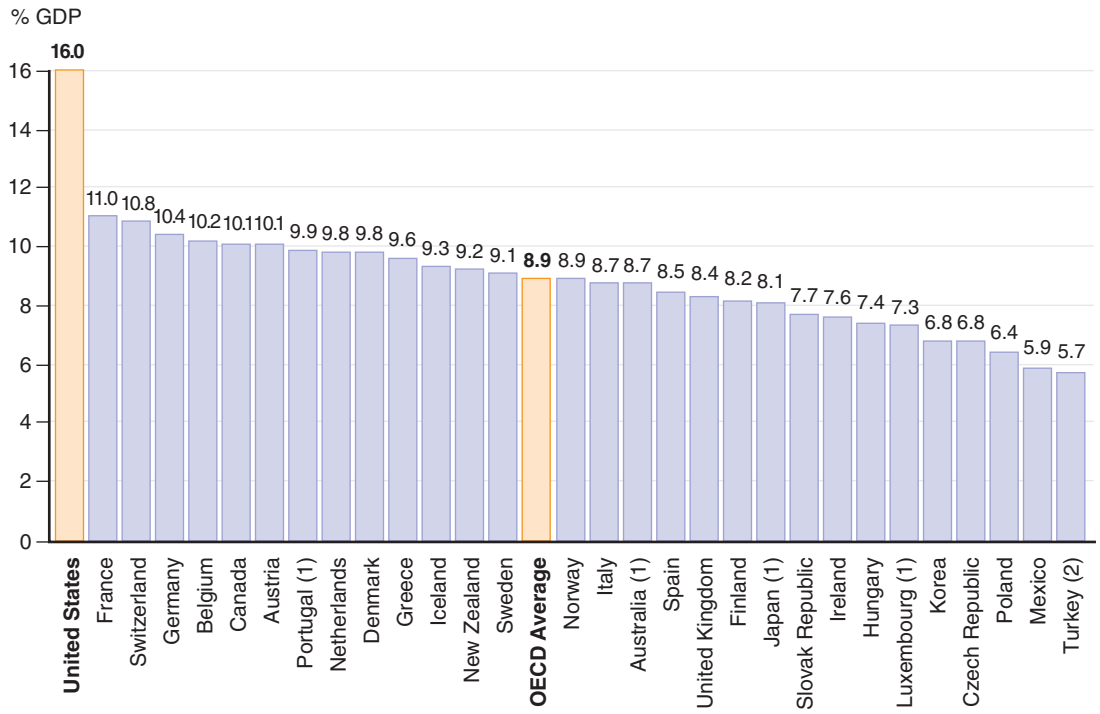

FIGURE 5-4. Health expenditure as a share of gross domestic product (GDP), 2007. OECD = Organisation for Economic Co-operation and Development. (Data from Organisation for Economic Co-operation and Development Health, 2009.)

physician work force relative to their population, as well as a much higher ratio of primary care physicians to specialists. The number of hospitals and hospital beds, the frequency of hospitalizations, and the length of hospital stay are relatively low in the United States, although it does have a much greater proportion of intensive care beds. Finally, recent analyses suggest that a principal driver of high expenditures on health care in the United States is the much greater price charged per unit of service compared with other developed countries.

Demand factors also drive medical expenditures. The extent to which the media and the medical profession feature medical "breakthroughs" is extensive and one-sided. New promising treatments merit front-page stories and commercial advertisements, whereas subsequent disappointing results are buried or ignored. The cumulative result is to whet patients' appetite for more and to leave the impression that good health depends only on finding the right treatment. This same quest explains the popularity of alternative medicine, for which patients are willing to spend $34 billion annually out of their own pockets (Chapter 38).

It could be argued that rising expenditures for medical care are not a bad thing, as what could be more important than ensuring maximal health? There are several rebuttals to that argument. First, it is not clear that money spent on medical care brings appropriate value in the United States, given that its health statistics are worse than those of virtually every other developed country. Second, there are substantial regional differences in the supply and use of medical care, such as a two-fold difference in the supply of acute hospital beds in metropolitan regions (even with adjustment for demographic variables) and a four-fold difference in the risk of being hospitalized in an intensive care unit at the end of life. Similar regional differences exist for procedures such as transurethral prostatectomy, hysterectomy, and coronary artery bypass surgery. Yet there is no evidence that "more is better" on a regional basis. In fact, geographic areas with higher consumption of medical services have been shown to have worse outcomes for some conditions, such as acute myocardial infarction.

Money spent on medical care means less to spend on other important social priorities—schools, the environment, job creation, and competition with overseas manufacturers that spend less on health care. Furthermore, many businesses are reducing their health insurance contributions to employees and retirees, passing those costs along to the beneficiaries. Consequently, health insurance coverage has emerged as the most important issue in labor contract negotiations and strikes. In addition, rising health care expenditures are stressing public programs such as Medicare, Medicaid, the Veterans Administration health system, and municipal hospitals, with budget requests outstripping the tax base to pay for them. Medical debt is by far the most important cause of bankruptcy. Finally, as health care becomes less affordable for businesses and government, the number of people without health insurance will continue to increase.

Since the mid-1970s, a variety of strategies to contain rising medical expenditures have yielded limited success. These attempts have tried to restrict the supply of costly medical technologies as well as the production of physicians, especially specialists; to promote health maintenance organizations that have incentives to spend less on medical care; to ration indirectly by limiting health insurance coverage; to institute prospective payment for hospital care; to use capitation payments or discounted fee schedules for physician reimbursement; to introduce gatekeeper mechanisms to reduce access to costly care; to put patients at more financial risk for their own medical care; to reform malpractice procedures; to reduce administrative costs; and to encourage less aggressive care at the end of life. The most recent suggestions—comparative effectiveness research to curtail unnecessary technology use, electronic medical records to avoid duplication of tests, and payment for performance—all hold the promise to improve quality, but their potential for substantial cost reduction is only theoretical at present. Fundamentally, all these strategies have failed because the political will to enforce them was missing. Americans—at least those with medical insurance—strongly resist limits on their choice of medical care, and the combined power of hospitals, medical professionals, and the pharmaceutical, medical device, and insurance industries overwhelms the meager forces pushing cost containment. Add to that the continuous production of new technologies and drugs plus the public's avidity for the latest innovations, and it is easy to see why medical costs are projected to keep rising. As a result, the costs of even modest health insurance plans are a challenge for most blue-collar and many middle-class families.

Payment for medical care varies by country. In the United States, health insurance coverage is an incomplete patchwork, consisting of government-sponsored programs for elderly people (Medicare), poor people (Medicaid), and veterans, plus employer-based coverage for workers and their families. Medicare covers acute care services in the hospital and in physicians' offices but has limited coverage for prescription drugs and long-term care. More than half of all Medicare subscribers also buy supplemental insurance. Medicaid covers more services than Medicare does, but Medicaid payments to physicians and hospitals are so low in many states that patients have restricted access to care. At any given time, more than 46 million Americans lack health insurance, and 70 million are without insurance at some point during the year. In addition, millions of immigrant workers are also uninsured. This large group must depend on charity care, often at community clinics and public hospitals, and it is well documented that lack of health insurance contributes to poor health, such as delayed diagnosis and undertreatment of asthma, diabetes, hypertension, and cancer.

The 2010 Patient Protection and Affordable Care Act (PPACA) contains insurance reform measures that took effect in 2010 and 2011, as well as coverage expansion that starts in 2014. About 32 million new people will be insured, about 50% privately and 50% in Medicaid. Revenue generating provisions are split about evenly between spending reductions and cost containment. In contrast to the passage of Medicare and Medicaid in 1965, the PPACA did not receive bipartisan support, and it is difficult to predict which of its components—if any—will survive.

Because medical care is both so valued and so expensive, physicians everywhere will inevitably become more involved in issues of medical economics. As cost-containment pressures force patients to assume more of their medical expenses, they will become more aware of costs and more demanding about the price and value of care. Informed clinical decision making will require that physicians have accurate information about the risks, benefits, and costs of medical care and better ways to communicate what is known and what is not.

APPROACH TO THE PATIENT: HISTORY AND PHYSICAL EXAMINATION

DAVID L. SIMEL

OVERVIEW

Physicians may have multiple objectives with varying degrees of importance in their encounters with patients. These goals include but are not limited to the translation of symptoms and signs into diagnoses, assessment of stability or change in known conditions, provision of information and counseling for future prevention, and reaffirmation or alteration of therapeutic interventions.

The interaction between the patient and physician represents not only a scientific encounter but also a social ritual centered on locus of control and meeting each other's expectations. Patients may not be able to express their needs fully and may fear loss of control in determining their own medical fate. Conversely, physicians have expectations: a need to feel that they have not missed something important in addressing diagnostic challenges, a need to put limits on the time available for each interaction, and a need to maintain objectivity so that their evaluation and recommendations are not clouded by their emotional feelings about the patient. When the patient needs to establish the presence of health or the diagnosis for a symptom, a physician's expertise is expressed through the performance and interpretation of a rational clinical examination.

Physical Examination Begins with the History

It is almost impossible to consider the history as distinct from the physical examination because the clinical examination begins as soon as the physician sees or hears the patient. Cynics contend that physical diagnostic skills have diminished in importance because so many diagnoses are made during the history and then confirmed by a laboratory value or a radiograph. The problem may be lack of practice in detecting physical examination findings with proven accuracy. Even proponents of the clinical examination now demand proof of reasonable reproducibility and accuracy before they accept the value of specific components of the history and physical examination.

Quantitative Principles of the Clinical Examination

Data on the sensitivity, specificity, likelihood ratios (LRs), and observer variability of components of the clinical examination can be obtained by a literature search for evaluation of a disease-specific condition (e.g., melanoma) or a clinical finding (e.g., splenomegaly) (Table 6-1). For each component of the history and physical examination, there is an associated sensitivity (the percentage of patients with a disorder who have an abnormal finding), specificity (the percentage of patients without a disorder who have a normal finding), and measure of precision (the agreement beyond chance between two observers) (Chapter 9). Current research on the clinical examination uses LRs that inform clinicians how likely they are to observe a particular finding in a patient with a given condition as opposed to a patient without the condition. A patient with an abnormal glabellar tap has an LR of 4.5 for Parkinson's disease (Chapter 416), which means that the risk for parkinsonism increases 4.5-fold compared with a patient with the baseline risk. Similarly, a patient who insists that he or she does not have "shaking in the arms" has an LR of 0.25 for Parkinson's disease and is one fourth as likely (a reduced chance) to have the disease compared with the baseline risk. Evaluation of the precision of the examination uses the kappa (κ) statistic to describe the agreement beyond chance (0 = random agreement; +1 = perfect agreement).

MEDICAL HISTORY

The history begins by asking patients to describe, in their own words, the reason for seeking medical care (Table 6-2). Although patients may have many reasons for initiating a visit to the physician, they should be encouraged to select the one or two most important concerns they have. The physician should reassure the patient that he or she will not ignore other concerns but wants to understand what is most important to the patient.

History of the Present Illness

Open-ended questions facilitate descriptions of problems in the patient's own words. Subsequently, specific questions fill in gaps and help clarify important points. These questions should be asked in an order dictated by the story the patient tells and targeted to suit the individual problem. When the patient is acutely ill, the physician should limit the amount of time spent in open-ended discussion and move promptly to the most important features that allow quick evaluation and management. In general, the history of the problem under consideration includes the following:

- Description of onset and chronology
- Location of symptoms
- Character (quality) of symptoms
- Intensity
- Precipitating, aggravating, and relieving factors
- Inquiry into whether the problem or similar problems occurred before and, if so, whether a diagnosis was established at that time

It is often helpful to ask patients to express what they believe is the cause of the problem or what concerns them the most. This approach often uncovers other pertinent factors and helps establish that the physician is trying to meet the patient's needs.

Past Medical and Surgical History

An astute clinician recognizes that patients may not report all their prior problems because they may forget, may assume that previous events are unrelated to their current problem, or simply may not want to discuss past events. Open-ended statements such as "Tell me about other medical illnesses that we did not discuss" and "Tell me about any operations you had" prompt the patient to consider other items. The physician should ask the patient about unexplained surgical or traumatic scars.

A list of current medications includes prescriptions, over-the-counter medications, vitamins, and herbal preparations. Patients who do not recall the names of medications should bring all medication bottles to the next visit. Patients may not consider topical medications (e.g., skin preparations or eyedrops) as important, so they may need prompting.

Information about allergies (Chapter 262) is particularly important, but challenging, to collect. Patients may attribute adverse reactions or intolerances to allergies, but many supposed allergic reactions are not truly drug allergies. Less than 20% of patients who claim a penicillin allergy are allergic on skin testing. Eliciting the patient's actual response to medications facilitates a determination of whether the response was a true allergic reaction.

Social and Occupational History and Risk Factors

The social history not only reveals important information but also improves understanding of the patient's unique values, support systems, and social situation. The social history should be tailored to the individual patient and allow for physician-centered questioning and patient-centered expression of values and concerns.

Data that may influence risk factors for disease should be gathered, including a nonjudgmental assessment of substance abuse. The tobacco history should include the use of snuff, chewing tobacco, and cigar and cigarette smoking (Chapter 31). Alcohol use should be determined quantitatively and by the effect that it has had on the patient's life (Chapter 32). Past or present use of illicit substances, prescription pain medications or sedatives, and intravenous drugs should be assessed (Chapter 33). The sexual history should address sexual orientation as well as current and past sexual activity (including the number of partners). The employment history should include the current and past employment history, military experience, and any significant hobbies. Military veterans should be asked about their combat history, years of service, and areas of deployment.

The physician should also obtain information on socioeconomic status, insurance, the ability to afford or obtain medications, and past or current barriers to health care because of their impact on care of the patient (Chapter 5). Marital status and the living situation (i.e., whom the patient lives with, significant stressors for that patient) are important as risk factors for disease and to determine how best to care for the patient. A patient's culture (Chapter 4) and values should be known, including any prior advance directives or desire to overrule them (Chapter 3). The physician should explicitly elicit and record information regarding the next of kin; surrogate decision makers; emergency contacts; social support systems; and financial, emotional, and physical support available to the patient.

TABLE 6-1 MEDLINE SEARCH STRATEGY FOR IDENTIFYING QUANTITATIVE INFORMATION ON THE CLINICAL EXAMINATION USING THE OVID SEARCH SYSTEM*

10. exp melanoma
11. 9 and 10
12. exp splenomegaly
13. 9 and 12

*OVID Technologies, Inc. A condition and a physical finding are given as examples. Abbreviations or search term abbreviations are as follows: "exp" indicates that the topic is "exploded" to include all subheadings for the topic. The "$" is a wildcard designator, so "exam$" would include the words *examination, examining,* and *examiner.* "mp" searches for the word or phrase in the title, abstract, registry number word, or mesh subject heading. Step 9 limits the search to studies that involve humans only and where the full manuscript is available online and is written in English. If the search yields too few topics, the limitation of full text available can be removed and the search repeated. If too many results are obtained, some of the items from step 8 can be eliminated.

TABLE 6-2 PATIENT'S MEDICAL HISTORY

Description of the patient
Age, gender, ethnic background, occupation
Chief reason for seeking medical care
State the purpose of the evaluation (usually in the patient's words)
Other physicians involved in the patient's care
Include the clinician that the patient identifies as his or her primary provider or the physician who referred the patient. Record contact information for all physicians who should receive information about the visit
History of the reason for seeking medical care
In chronologic fashion, determine the evolution of the indication for the visit and then each major symptom. It is best to address the patient's reason for seeking care first rather than what the physician ultimately believes is most important
Be careful to avoid "premature closure," in which a diagnosis is assumed before all the information is collected
Past medical and surgical history
List other illnesses and previous surgeries not related to the current problem
List all prescribed and over-the-counter medications with dose
Remember to ask about vitamin and herbal supplements
Allergies and adverse reactions
List allergic reactions to medications and food. Record the specific reaction (e.g., hives). Distinguish allergies from adverse reactions or intolerance to medication (e.g., dyspepsia from nonsteroidal anti-inflammatory agents)
Social and occupational history
Describe the patient's current family and a typical day for patient. The occupational history should focus on current and past employment as it might relate to the current problem. For veterans, inquire about their military history, including combat exposure, years of service, and areas of deployment
Risk factors
Include history of tobacco use, illegal drug use, and risk factors for sexually transmitted disease (including human immunodeficiency virus and hepatitis)
Family history
History of any diseases in first-degree relatives and a listing of family members with any conditions that could be risk factors for the patient (e.g., cardiovascular disease at a young age, malignancy, known genetic disorders, longevity)
Review of systems (see Table 6-3)

Family History

The family history is never diagnostic, but it allows risk stratification, which affects the pretest probability for an increasing number of disorders (e.g., heart disease, breast cancer, or Alzheimer's disease). For common diseases such as heart disease, additional inquiry into the age of onset in first-degree relatives and death attributed to the disease should be obtained (Chapter 51). When a patient reports that a first-degree relative had a myocardial infarction, the LR is 19 that the patient has a family history of myocardial infarction. Patients may lack appropriate information about the absence of disease, however, so a reported lack of a family history of myocardial infarction reduces the likelihood only by one third. In general, the specificity of the reported family history far exceeds its sensitivity; for example, only two thirds of patients with essential tremor (Chapter 417) report a family history, but 95% of such patients have first-degree relatives with tremor. The expansion of knowledge about genetic diseases (Chapter 39) requires clinicians not only to improve their skills in eliciting the family history but also to develop methods for confirming the information. For example, patients who report that a first-degree relative had carcinoma of the colon (LR 25), breast (LR 14), ovaries (LR 34), or prostate (LR 12) are usually providing accurate information.

TABLE 6-3 REVIEW OF SYSTEMS*

FOCUS all questions on a specific time frame (e.g., within the past "month" or "now") and on items not already addressed during the clinical examination
Change in weight or appetite
Change in vision
Change in hearing
New or changing skin lesions
Chest discomfort or sensation of skipped beats
Shortness of breath, dyspnea on exertion
Abdominal discomfort, constipation, melena, hematochezia, diarrhea
Difficulty with urination
Change in menses
Joint or muscle discomfort not already mentioned
Problems with sleep
Difficulty with sexual function
Exposure to "street" drugs or medications not already mentioned
Depression (feeling "down, depressed, or hopeless"; loss of interest or pleasure in doing things)
A sensation of unsteadiness when walking, standing, or getting up from a chair

*Clinicians may start with this basic list and adapt the items to their specific patient population by considering factors such as age, gender, medications, and the problems identified during the examination. The process is facilitated by developing a routine personal approach to these questions, typically going through the systems from "head to toe."

Review of Systems

The review of systems, which is the structural assessment of each of the major organ systems, elicits symptoms or signs not covered, or overlooked, in the history of the present illness. In practice, the review of systems may be accomplished by direct questioning (Table 6-3) or by having the patient fill out a previsit questionnaire that constrains the answers to a specific time frame. When this review is directly obtained, physicians should not use open-ended questions but rather proceed with direct questions, such as "Has there been any recent change in your vision?" or "Have you recently had shortness of breath, wheezing, or coughing?" The relative value of these approaches has not been investigated fully, but restricting the symptoms to a narrower time frame prevents a complete retelling of the history. One estimate is that the review of systems yields a new important diagnosis about 10% of the time.

PHYSICAL EXAMINATION

Chaperones

Surveys suggest that most patients of either sex and all ages report a lack of preference for a chaperone; it is not clear whether this response is their true feeling or a desire to give a "correct" response. Nevertheless, many adult women (29%) and adolescent girls (46%) do express a preference for a chaperone during a breast, pelvic, or rectal examination by a male physician (especially during their first examination). Examiners should offer patients the option of a chaperone, and a chaperone should be considered when the clinician and patient are of different genders. Many examiners prefer a chaperone to allay their own anxieties attributable to gender differences or to achieve a perceived need for protection should the patient become concerned during the procedure.

Vital Signs

Vital signs include the pulse rate, blood pressure, respiratory rate, body temperature, and the patient's quantitative assessment of pain. Marked abnormalities require a rapid, focused evaluation that may take precedence over the typical structural approach to the remainder of the evaluation (Chapter 7).

The pulse should be recorded as not just the rate but also the rhythm. Physicians may prefer to initiate the examination by holding the patient's hand while palpating the pulse. This nonthreatening initial contact with the

patient allows the physician to determine whether the patient has a regular or irregular rhythm.

When the blood pressure is abnormal (Chapter 67), the measurement should be repeated, assuring that the cuff size is appropriate. Many adults require a large adult cuff; using a narrow cuff can alter systolic/diastolic blood pressure by −8 to +10/+2 to +8 mm Hg. The appearance of repetitive sounds (Korotkoff sounds, phase 1) constitutes systolic pressure. (Record the value rounded upward to the nearest 2 mm Hg.) After the cuff is inflated about 20 to 30 mm Hg above the palpated pressure, the Korotkoff sounds muffle and disappear as the pressure is released (phase 5). The level at which the sounds disappear is diastolic pressure.

Respirations should be assessed with the patient unaware that the rate is being observed. The examiner should decide whether patients have tachypnea (a rapid rate of breathing) or hypopnea (a slow or shallow rate of breathing). Tachypnea is not always associated with hyperventilation, which is defined by increased alveolar ventilation resulting in a lower arterial carbon dioxide level (Chapter 103). In the evaluation of patients suspected of having pneumonia, examiners agree on the presence of tachypnea only 63% of the time. The subjective sensation of dyspnea (Chapter 83) is caused by an increased work of breathing.

The body temperature of adults is measured with an oral electric thermometer. Rectal thermometers reliably record temperatures 0.4° C higher than oral thermometers. Tympanic thermometers may vary too much in comparison to oral thermometers (−1.2° to +1.6° C vs. the oral temperature) to be reliable in hospitalized patients.

As a vital sign measure, patients should self-rate any pain on a scale of 0 to 10 (no pain to worst pain ever) (Chapter 29). However, the validity, usefulness, and value of this approach as a screening tool for clinical diagnosis are uncertain.

Head and Neck

Face

The examiner can simplify the assessment by carefully judging for facial symmetry. Asymmetrical facial features should be noted and explained. Examples of asymmetry include skin lesions (Chapter 444), cranial nerve palsies (Chapter 403), parotid enlargement (Chapter 433), or the ptosis of Horner's syndrome (Chapter 432). A variety of disorders may cause symmetrical, abnormal facies; examples include acromegaly (Chapter 231), Cushing's syndrome (Chapter 234), and Parkinson's disease (Chapter 416).

Ears

Physicians may not recognize their patient's hearing impairment (Chapter 436). The inability to appreciate the whispered voice increases the likelihood of hearing loss (LR 6). Otoscopic evaluation of the tympanic membranes should reveal a translucent membrane and an obvious cone of light reflected where the eardrum meets the malleolus (see Fig. 434-6). Cerumen impaction is an easily treated cause of diminished hearing.

Nose

Patients frequently have nasal symptoms, such as a self-diagnosis of sinusitis (Chapter 434) or snoring (Chapter 412). The nares should be examined for the presence of polyps, which can be seen as obstructing, glistening mucosal masses. Transillumination performed in a dark room is useful for diagnosing sinusitis, especially when combined with visualization of a purulent discharge, a patient's report of a poor response to decongestants or antihistamines, a maxillary toothache, and the presence of discolored rhinorrhea (Chapter 434). These patients have an LR greater than 6 for rhinosinusitis.

Mouth

The quality of the patient's dentition directly affects nutrition. Generalist physicians can be confident that the patient requires dental care if periodontal disease or dental caries are detected (LR > 4). Premalignant oral lesions (e.g., leukoplakia [see Fig. 196-1], nodules, ulcerations) found by generalist physicians are usually verified by dentists (LR > 6.5) (Chapter 433). Patients who use smokeless tobacco products are at significantly increased risk for premalignant and malignant oral lesions (Chapter 31). Bimanual palpation of the cheeks and floor of the mouth facilitates identification of potentially malignant lesions (Chapter 433).

Eyes

The eye examination begins with simple visual inspection to look for symmetry in the lids, extraocular movements, pupil size and reaction, and the presence of redness (Chapters 431 and 432). Abnormalities in extraocular movements should be grouped into nonparalytic (usually chronic with onset in childhood) or paralytic causes (third, fourth, or sixth cranial nerve palsy). Pupillary abnormalities may be symmetrical or asymmetrical (anisocoria). Red eyes should be categorized by the pattern of ciliary injection, presence of pain, effect on vision, and papillary abnormalities. When the eye examination is approached systematically, the generalist physician can evaluate the likelihood of conjunctivitis, episcleritis or scleritis, iritis, and acute glaucoma.

Routine determination of visual acuity can help confirm or refute a patient's report of diminished vision but does not replace the need for formal ophthalmologic evaluation in patients with visual complaints (Chapter 431). Cataracts can be detected with direct ophthalmoscopy, but the generalist's proficiency in this evaluation is uncertain.

After identifying the optic disc by ophthalmoscopy, the examiner should note the border of the disc for clarity, color, and the size of the central cup in relation to the total diameter (usually less than half the diameter of the disc). A careful observer usually can see spontaneous venous pulsations that indicate normal intracranial pressure, but about 10% of patients with normal intracranial pressure will not have spontaneous pulsations. Abnormalities of the optic disc include optic atrophy (a white disc), papilledema (see Fig. 431-27) (blurry margins with a pink, hyperemic disc), and glaucoma (a large, pale cup with retinal vessels that dive underneath and that may be displaced toward the nasal side). The generalist's examination inadequately detects early glaucomatous changes, so high-risk patients should undergo routine ophthalmologic examination for glaucoma.

After inspecting the disc, the examiner should examine the upper and lower nasal quadrants for the appearance of vessels and the presence of any retinal hemorrhages (see Fig. 431-24) or lesions. Proceeding from the nasal quadrants to the temporal quadrants decreases the risk of papillary constriction from the bright light focused on the fovea. Dilating the pupils leads to an improved examination. Patients with diabetes (Chapter 236) should undergo routine examination by eye care experts because the sensitivity of a generalist's examination is not adequate to exclude diabetic retinopathy or monitor it over time.

Neck

Carotid Pulses

The carotid pulses should be palpated for contour and timing in relation to the cardiac impulse. Abnormalities in the carotid pulse contour reflect underlying cardiac abnormalities (e.g., aortic stenosis) but are generally appreciated only after detecting an abnormal cardiac impulse or murmur (Chapter 50).

Many physicians listen for bruits over the carotid arteries because asymptomatic carotid bruits are associated with an increased incidence of cerebrovascular and cardiac events in older patients (Chapters 413 and 414). In asymptomatic patients, the presence of a carotid bruit increases the likelihood of a 70 to 90% stenotic lesion (LR 4 to 10), but the absence of a bruit is of uncertain value. Unfortunately, clinical data do not provide adequate data for judging the importance of detecting bruits in asymptomatic patients.

Thyroid

The thyroid gland is felt best when standing behind the patient and using both hands to palpate the thyroid gland gently (Chapter 233). The palpatory examination is enhanced by asking the patient to swallow sips of water, which allows the thyroid to glide underneath the fingers. When viewed from the side, lateral prominence of the thyroid between the cricoid cartilage and the suprasternal notch indicates thyromegaly. The generalist physician should estimate the size of the thyroid gland as normal or enlarged; the impression of an enlarged thyroid gland by a generalist physician has an LR of almost 4, whereas assessment of normal size makes thyromegaly less likely (LR 0.4).

Lymphatic System

While palpating the thyroid, the examiner may also identify enlarged cervical lymph nodes (Chapter 171). Lymph nodes can also be palpated in the supraclavicular area, axilla, epitrochlear area, and inguinofemoral region. Simple lymph node enlargement confined to one region is common and does not usually represent an important underlying disorder. Unexpected gross lymph node enlargement in a single area or diffuse lymph node enlargement is more important. Patients with febrile illnesses, underlying malignancy, or inflammatory diseases should routinely undergo an examination of each of the aforementioned areas for lymph node enlargement.

Chest

Inspection of the patient's posture may reveal lateral curves in the back (scoliosis) or kyphosis that may be associated with loss of vertebral height from osteoporosis (Chapter 251). When patients have back pain, the spine and paravertebral muscles should be palpated for spasm and tenderness (Chapter 407). The patient may be placed through maneuvers to assess loss of mobility associated with ankylosing spondylitis (Chapter 273), but a history of loss of lateral mobility may be just as efficient in the early stages of spondylitis.

Lungs

Examination of the lungs begins with inspection for chest deformities. A barrel chest, thought to be typical of obstructive airways disease, is present only in severely affected patients (Chapters 83 and 88). The incremental value of palpation and percussion of the chest to supplement the history, auscultation, and eventual chest radiograph is unknown. Medical students show more consistency than pulmonary specialists do in recording auscultatory abnormalities. The presence or absence of adventitial sounds (wheezes, crackles, or rubs) has good interobserver reliability (κ 0.30 to 0.70). The best piece of information for increasing the likelihood of chronic obstructive pulmonary disease is a history of more than 40 pack years of smoking (LR 19). The presence of wheezing or downward displacement of the larynx to within 4 cm of the sternum (distance between the top of the thyroid cartilage and the suprasternal notch) increases the likelihood of obstructive pulmonary disease (LR of 4 for either). Auscultated wheezes are continuous sounds. Crackles (formerly called rales) are discontinuous lung sounds heard in conditions that create lung stiffening (heart failure, pulmonary fibrosis, and obstructive lung disease).

Heart

The patient should be examined in the sitting and lying positions (Chapter 50). Palpation of the apical impulse in the left lateral decubitus position helps detect a displaced apical impulse and can reveal a palpable S_3 gallop. When the apical impulse is lateral to the midclavicular line, radiographic cardiomegaly (LR 3.5) and an ejection fraction of less than 50% (LR 6) are more likely. Most examiners auscultate in sequence the aortic area, pulmonic area, left sternal border, and apex. First, listen to the heart sounds and concentrate on their timing, intensity, and splitting with respiration. The first and second heart sounds are heard best with the diaphragm, as are pericardial rubs. Gallops (S_3 and S_4) are heard best with the stethoscope bell. High-pitched versus low-pitched murmurs are detected by switching from the diaphragm to the bell (see Table 50-6). The location, timing, intensity, radiation patterns, and respiratory variation of murmurs should be noted. Special maneuvers during auscultation (e.g., Valsalva, auscultation during sudden squatting or standing) do not usually need to be performed if the results of routine precordial examination are entirely normal.

There is considerable concern about the reliability and accuracy of the cardiac examination. When performed on patients (as opposed to cardiac simulators), the reliability of perceiving an S_3 or S_4 is no better than chance, and agreement on the finding among examiners does not seem to improve with the examiner's experience. Nevertheless, the presence of an S_3 on any examination is useful for detecting left ventricular systolic dysfunction (LR > 4 for identifying patients with an ejection fraction <30%). The presence of a systolic thrill (palpable murmur, LR 12) or a holosystolic murmur increases the likelihood of moderate to severe aortic stenosis or mitral regurgitation. Quiet systolic murmurs (LR 0.08) are much less likely to herald important cardiac abnormalities. A loud, early diastolic murmur (LR 4) or a diastolic murmur associated with an S_3 suggests severe aortic regurgitation.

Breast

The most important determinants of the accuracy of the breast examination are the duration of the examination; the patient's position; careful evaluation of the breast boundaries; the pattern of the examination; and the position, movement, and pressure of the examiner's fingers (Chapter 204). Interobserver variability is substantial (κ about 0.3 to 0.6) because these aspects of the examination vary among physicians. To obtain the best sensitivity, the duration of the breast examination needs to be 5 to 10 minutes' total time, but few generalist physicians perform such a lengthy examination. Clinicians should recognize that the examination may make them (or their patient) feel uncomfortable—the presence of a chaperone may give the clinician the confidence to perform an intensive examination.

The patient should be examined with the pads of the fingers while she is supine, holding her hand first on her forehead (to flatten the lateral border of the breast) and then on her shoulder (to flatten the medial border). The examiner should make small circular motions with the fingers, moving up and down in parallel rows to span the entire breast-clavicle to the bra line. Cancerous breast lumps are difficult to distinguish from benign breast lumps on examination, but the presence of a fixed mass or a mass 2 cm in diameter has an LR of about 2 to 2.5 for cancer.

Abdomen

When patients have potential abdominal symptoms and the history suggests an acute problem, the examination should focus initially on identifying patients who may require surgical evaluation. Palpation and percussion of the abdomen of patients with no symptoms or risk factors for an abdominal disorder seldom reveal important abnormalities (Chapter 134) except for asymptomatic widening of the abdominal aorta in older patients (LR of 16 for detecting aneurysms >4 cm in diameter). However, palpation misses a substantial proportion of small to medium aneurysms (Chapter 78). After specific training in palpation techniques, general internists have good agreement on the presence or absence of an aortic aneurysm ($\kappa = 0.53$).

The presence of bowel sounds in patients with acute symptoms can be falsely reassuring because bowel sounds can be present despite an ileus and may be increased early in an obstruction. For patients without gastrointestinal symptoms or abnormalities on palpation, auscultation for bruits is important primarily to detect renal bruits in patients with hypertension (Chapters 67 and 127). The presence of an abdominal bruit in a hypertensive patient, if heard in systole and diastole, strongly suggests renovascular hypertension (LR $\approx$ 40).

Liver

Detection of liver disease depends mostly on the history and laboratory evaluations (Chapter 148). By the time that signs are present on physical examination, the patient usually has advanced liver disease. The first abnormalities on physical examination associated with liver disease are extrahepatic. The clinician should assess the patient for ascites, peripheral edema, jaundice, or splenomegaly as signs of liver disease. In patients with an enlarged liver, palpation should begin at the liver edge, but palpation of the edge below the costal margin increases the likelihood of hepatomegaly only slightly (LR 1.7). The upper border of the liver may be detected by percussion, and a span of less than 12 cm reduces the likelihood of hepatomegaly. In the absence of a known diagnosis (e.g., a hepatoma, which may cause a hepatic bruit), auscultation of the liver rarely is helpful.

Spleen

Examination for splenomegaly in patients without findings suggestive of a disorder associated with splenomegaly almost always reveals nothing (Chapter 171). Approximately 3% of healthy teenagers may have a palpable spleen. The examination for an enlarged spleen begins first with percussion in the left upper quadrant to detect dullness. Percussion is performed over the lowest left anterior axillary line during inspiration and expiration while the patient is supine. In the absence of dullness, the results of palpation do not establish or exclude splenomegaly, so a radiographic image (ultrasound or nuclear scintigraphy) is required. The presence of a palpable splenic edge in patients with dullness to percussion and clinical suspicion of splenomegaly confirms enlargement. Palpation can be performed by any of the following three approaches (κ about 0.2 to 0.4): palpating with the right hand while providing counterpressure with the left hand behind the spleen, palpating with one hand without counterpressure (with the patient in the right lateral decubitus position for both techniques), or placing the patient supine with the left fist under the left costovertebral angle while the examiner tries to hook the spleen with the hands.

Musculoskeletal System

The musculoskeletal examination in adult patients is almost always driven by symptoms (Chapters 264 and 271). Most patients have back pain at some point during their lives (Chapter 407). Back pain is second only to upper respiratory illness as a reason for seeking outpatient care. Most patients' musculoskeletal discomfort will be self limited. The patient's history helps assess the likelihood of an underlying systemic disease (age, history of systemic malignancy, unexplained weight loss, duration of pain, responsiveness to previous therapy, intravenous drug use, urinary infection, or fever). The most important physical examination findings for lumbar disc herniation in

patients with sciatica all have excellent reliability, including ipsilateral straight leg raising causing pain, contralateral straight leg raising causing pain, and ankle or great toe dorsiflexion weakness (all with $\kappa > 0.6$).

The generalist physician should evaluate an adult patient with knee discomfort for torn menisci or ligaments. The best maneuver for demonstrating a tear in the anterior cruciate ligament is the anterior drawer or Lachman maneuver, in which the examiner detects the lack of a discrete end point as the tibia is pulled toward the examiner while the femur is stabilized. A variety of maneuvers that assess for pain, popping, or grinding along the joint line between the femur and tibia are used to evaluate for meniscal tears. As with many musculoskeletal disorders, no single finding has the accuracy of the orthopedist's examination, which factors in the history and a variety of clinical findings.

The shoulder examination is directed toward determining range of motion, maneuvers that cause discomfort, and assessment of functional disability. Hip osteoarthritis is detected by evidence of restriction of internal rotation and abduction of the affected hip. Generalist physicians often rely on radiographs to determine the need for referral to orthopedic physicians, but routine radiographs are not needed early in the course of shoulder or hip disorders. The degree of pain and disability experienced by the patient may prompt confirmation of the diagnosis and referral.

The hands and feet may show evidence of osteoarthritis (local or as part of a systemic process) (Chapter 270), rheumatoid arthritis (Chapter 272), gout (Chapter 281), or other connective tissue diseases. In addition to regional musculoskeletal disorders, such as carpal tunnel syndrome, a variety of medical and neurologic conditions should prompt routine examination of the distal ends of the extremities to prevent complications (e.g., diabetes [neuropathy or ulcers] or hereditary sensorimotor neuropathy [claw toe deformity]).

Skin

The skin should be examined under good lighting (Chapter 444). It is best to ask the patient to point out any spots on the skin of concern. Examiner agreement on some of the most important features of melanoma (asymmetry, haphazard color, border irregularity) is fair to moderate (Chapter 210). A lesion that is symmetrical, has regular borders, is only one color, is 6 mm or smaller, or has not enlarged in size is unlikely to represent a melanoma (LR 0.07). However, an increasing number of findings greatly enhances the likelihood of melanoma (LR 2.6 for two or more findings and LR 98 for the presence of all five findings) (Chapter 210).

Basal cell carcinoma and squamous cell carcinoma occur even more frequently than melanoma (Chapter 210). These lesions can be detected during routine examination by paying careful attention to sun-exposed areas of the nose, face, forearms, and hands.

Neurologic Examination

Full details of the neurologic examination are given in Chapter 403.

Psychiatric Evaluation

During the general examination, much of the psychiatric assessment (including cognition) is accomplished while eliciting the routine history and performing the review of systems (Chapter 404). Observation of the patient's mannerisms, affect, facial expression, and behavior may suggest underlying psychiatric disturbances. When a screening survey and review of systems are obtained by a questionnaire completed by the patient, the clinician should review the responses carefully to determine whether the patient exhibits symptoms of depression. Specific questioning for symptoms of depression is appropriate for all adult patients. Military veterans should be screened for post-traumatic stress disorder and possible prior traumatic brain injuries that may affect their behaviors. Delirium (Chapter 27) is common in both medical and surgical inpatients and is recognized by fluctuating mental status.

Genitalia and Rectum

Pelvic Examination

A complete examination includes a description of the external genitalia, appearance of the vagina and cervix as seen through a speculum, and bimanual palpation of the uterus and ovaries (Chapters 205 and 245). The precision of the pelvic examination is uncertain. In the emergency setting, there is poor agreement between resident physicians and emergency physicians on the presence of cervical motion tenderness, uterine tenderness, adnexal tenderness, and adnexal masses (κ about equal to 0.2 to 0.25) (Chapter 293). Among gynecologists, assessment of uterine size by examination correlates reasonably well with measurement by pelvic ultrasound. Of asymptomatic women, 10 to 15% have some abnormality on examination, and 1.5% have abnormal ovaries. Screening for ovarian cancer is limited by the low sensitivity of the physical examination for detecting early-stage ovarian carcinoma (Chapter 205).

Male Genitalia

Examination of the male genitalia should begin with a description of whether the penis is circumcised and whether there are any visible skin lesions (e.g., ulcers or warts). Palpation should confirm the presence of bilateral testes in the scrotum. The epididymis and testes should be palpated for nodules. The low incidence of testicular carcinoma means than most nodules are benign (Chapter 206).

The prostate should be examined in all quadrants with attention focused on surface irregularities or differences in consistency throughout the prostate (Chapter 207). An estimate of prostate size may be confounded by the size of the examiner's fingers. It may be best to estimate the size of the prostate in centimeters of width and height.

Rectum

Patients can be examined while lying on their side, although this approach may place the examiner in an awkward stance (Chapters 134 and 147). The rectal examination in women can be performed as part of a bimanual examination, with the index finger in the vagina and the third finger in the rectum to permit palpation of the rectovaginal vault. Men may be asked to stand and lean over the examining table; alternatively, they may be examined while on their back with their hips and knees flexed. This latter maneuver is not used often, although it may facilitate examination of the prostate, which falls into the finger in this position.

The rectal examination begins with inspection of the perianal area for skin lesions. A well-lubricated, gloved finger is placed on the anus, and while applying gentle pressure, the examiner asks that the patient bear down as though having a bowel movement. This maneuver facilitates entry of the finger into the rectum. A normal rectal response includes tightening of the anal sphincter around the finger. The examiner should palpate circumferentially around the length of the fully inserted finger for masses. On withdrawing the gloved finger, the finger should be wiped on a stool guaiac card for fecal blood testing to assess for acute blood loss. As a screening test for colorectal carcinoma (Chapter 199), digital examination does not replace the need for testing stool samples collected by the patient (or using alternative screening strategies, such as flexible sigmoidoscopy or colonoscopy).

SUMMARIZING THE FINDINGS FOR THE PATIENT

The physician should summarize the pertinent positive and negative findings for the patient and be willing to express uncertainty to the patient, provided that it is accompanied by a plan of action (e.g., "I will reexamine you on your next visit"). The rationale for subsequent laboratory, imaging, or other tests should be explained. A plan should be established for providing further feedback and results to the patient, especially when there is a possibility that bad news may need to be delivered. Some physicians ask the patient if there is "anything else" to be covered. Patients who express additional new concerns at the end of the visit may have been fearful to address them earlier (e.g., "by the way, doctor, I'm getting a lot of chest pain"); when the problems seem non-urgent, it is acceptable to reassure the patient and offer the promise of evaluating them in a follow-up phone call or at the next visit.

FUTURE DIRECTIONS

The common assumption that physicians' diagnostic skills are deteriorating is not supported by evidence. There is considerable evidence that the scientific approach to understanding what is worthwhile and what is not worthwhile during the clinical examination identifies a core set of skills for clinical diagnosticians. Because good patient outcomes at good value are driven primarily by the quality of the information obtained during the clinical examination, continued application of scientific principles to the history and physical examination should improve diagnostic skills.

APPROACH TO THE PATIENT WITH ABNORMAL VITAL SIGNS

DAVID L. SCHRIGER

Care of the patient is guided by integration of the chief complaint, history, vital signs, and physical examination findings (Chapter 6). Physicians should be keenly aware of a patient's vital signs but should seldom make them the centerpiece of the evaluation.

THE IMPORTANCE OF VITAL SIGNS

The importance of vital signs in medical care is a conundrum for proponents of an evidence-based approach to care of patients. No experienced physician would be willing to care for patients without them, yet a formal evaluation of the utility of vital signs for making specific diagnoses would conclude that they are not particularly useful because their likelihood ratios are too low to differentiate those who have a condition from those who do not (Chapter 6). For uncommon conditions, their predictive value is even worse. For example, the probability of tachycardia in a patient in thyroid storm is high, yet the probability of thyroid storm in a patient with isolated tachycardia is low. This application of Bayes' theorem (Chapter 9) demonstrates why there is no justification for ordering thyroid tests for every tachycardic patient and why attempts to say "When vital sign *x* is high [low], do *y*" fail. Each vital sign can be normal or abnormal in almost every acute condition (Table 7-1), and vital signs can be transiently abnormal in healthy individuals. An algorithmic approach to testing and treatment in response to abnormal vital signs would be too vague and too complex to be of use.

Predictive Value

How can it be that vital signs are poor predictors of diagnoses but central to the practice of medicine? First, although vital signs are insufficiently predictive to be of use in rigid algorithms, these algorithms are but one of several heuristics used by physicians to diagnose and to treat patients. Pattern recognition and the hypothetical-deductive model are heuristics that are based not on average tendencies of a single factor (e.g., hypotension is present in *x*% of cases of septic shock) or a small number of factors (hypotension and tachycardia are present in *y*% of cases of septic shock) but on the complex interaction of multiple factors (e.g., because this patient is an ill-appearing elderly man with an enlarged prostate and a history of urinary tract infections, is tachycardic and hypotensive, has clear lungs and an enlarged but nontender prostate, and has an oxygen saturation of 97%, he should be treated for urosepsis [Chapter 292] while awaiting results of urinalysis and urine culture).

TABLE 7-1 NORMAL AND PANIC RANGES FOR KEY VITAL SIGNS IN ADULTS*

	NORMAL	PANIC
Temperature	36°-38° C (96.8°-100.4° F)	40° C (104° F)
Pulse	60-100 beats/min	<45 beats/min, >130 beats/min
Respirations	12-20 breaths/min	<10 breaths/min, >26 breaths/min
Oxygen saturation	95-100%	<90%
Systolic blood pressure	90-130 mm Hg	<80 mm Hg, >200 mm Hg
Diastolic blood pressure	60-90 mm Hg	<55 mm Hg, >120 mm Hg

*Normal values are for healthy adults. Values outside these ranges are common in patients who are ill or are anxious about their health care encounter. Panic values demand the health care provider's attention in any adult patient. These values are specific (rarely present in healthy patients) but not sensitive (most ill patients' vital signs will not include panic values). All vital signs must be interpreted in the context of the patient's presentation (see text).

Thus, vital signs can play an important function in medical decision making even though their likelihood ratios for specific complications are unimpressive. In one study, for example, the 16% of medical and surgical ward patients with abnormal vital signs had a 20-fold higher rate of transfer to a higher level of care, cardiac arrest, or death compared with patients with persistently normal vital signs.

Vital Signs as Symptoms

Abnormal vital signs are seldom the fundamental pathophysiologic problem. In shock (Chapter 106), hypotension and tachycardia are manifestations of pathophysiologic processes occurring at cellular and molecular levels. Given the circuitous links from clinical disease to fundamental pathophysiology to abnormal vital signs, it is not surprising that the relationships between the disease states and vital signs are not strong. Until new technologies enable direct measurement of primary pathologic processes, vital signs remain an important, albeit imperfect, proxy.

The five key vital signs are temperature, pulse, blood pressure, respiratory rate, and oxygen saturation (pulse oximetry). Pulse oximetry is included because it has become widely available in acute care settings, is noninvasive and relatively inexpensive, and provides information unique from the respiratory rate. Advocates have suggested that pain, smoking status, and weight be considered routine vital signs; although a case can be made for each, they are not considered here. Clinicians should never forget that the most important vital sign is what the patient looks like; general appearance is a sign that guides the intensity and urgency of the evaluation.

MEASURING VITAL SIGNS

Although obtaining vital signs is generally straightforward, the validity and reliability of measurement depend on proper technique and, for blood pressure and pulse oximetry, well-maintained equipment. Rectal and oral temperatures are generally accurate (Chapter 288), although oral temperatures can be falsely depressed in patients who breathe through their mouths. Axillary temperature is unreliable and should not be used. There is wide variability in the validity and reliability of measurements performed with tympanic membrane thermometers. A hypothermia thermometer is preferred in patients with suspected hypothermia, and core temperature should be measured with an esophageal, bladder, or rectal temperature sensor in patients with severe hypothermia or hyperthermia (Chapter 109).

Blood pressure must be measured with an appropriately sized cuff (Chapter 67). Automated blood pressure machines occasionally provide spurious results, and questionable values should be confirmed by manual auscultation and by checking other limbs. Pulse is best obtained by palpation because this technique provides the opportunity to assess regularity and contour; the pulse should be counted for sufficient time for an accurate rate to be obtained (at least 15 seconds). High heart rates on the readout of a cardiac monitor must be confirmed by palpation because these monitors can spuriously count large P waves, T waves, or pacemaker spikes as R waves, thereby reporting a heart rate double the actual rate. Orthostatic vital signs—the comparison of blood pressure and pulse in the supine, sitting, and standing positions—are advocated by some but have proved to be insensitive and nonspecific for hypovolemia.

Because the typical respiratory rate is between 12 and 20 breaths per minute and because there is considerable breath to breath variation, the respiratory rate should be assessed for at least 30 seconds and preferably 1 minute. Oxygen saturation is dependent on technology, so an understanding of the idiosyncrasies of the device being used is critical; valid measurements are unlikely unless there is good correlation of the machine's pulse reading and the patient's pulse. The probe should be placed on a part of the body that is warm and well perfused. Pulse oximeters compare the absorption of light at two wavelengths, so readings may be spuriously high under conditions that change the color of oxygenated or deoxygenated hemoglobin, including carbon monoxide poisoning (Chapter 94), methemoglobinemia (Chapter 164), and some of the less common hemoglobinopathies.

ROLE OF VITAL SIGNS IN MANAGEMENT OF THE PATIENT

Abnormal vital signs should be remeasured. Certain abnormalities require prompt evaluation (Table 7-2). Other vital sign abnormalities should be rechecked in the future unless they have been previously noted, in which case a work-up can be initiated, guided by the patient's past history and physical examination findings. It is critical that the physician always "treat the patient, not the vital signs."

TABLE 7-2 ABNORMALITIES REQUIRING RAPID EVALUATION IN THE ASYMPTOMATIC PATIENT

An irregularly irregular rapid pulse (if it is not known to be chronic) should trigger an evaluation of the patient's rhythm so that atrial fibrillation can be identified, evaluated, and treated (Chapter 64), thereby decreasing the patient's risk of stroke.

A heart rate above 130 beats/min warrants an electrocardiogram to determine the patient's rhythm and a consideration of the differential diagnosis of tachycardia (anemia and thyroid disease in particular).

A markedly elevated diastolic blood pressure (e.g., >115 mm Hg) should stimulate an evaluation for hypertensive urgencies (Chapter 67). Note that hypertension in the absence of signs of acute end-organ damage does not require acute treatment, which can reduce intracranial perfusion pressure and cause stroke. Patients with elevated blood pressure should be offered standard evaluation and treatment for chronic hypertension (Chapter 67).

Markedly low pulse or blood pressure in patients receiving cardioactive medications should lead to a confirmation that the patient is truly asymptomatic, an inquiry into the dosing of these medications, and a reconsideration of the regimen.

Markedly low pulse in elderly patients who are not receiving rate-controlling drugs should trigger an evaluation of the patient's cardiac conduction system.

Oxygen saturation below 93% in the absence of known pulmonary problems should prompt an evaluation of the patient's pulmonary status.

Patients without Systemic Complaints

In patients presenting for a routine evaluation or nonsystemic complaint (e.g., knee pain), an abnormal vital sign will seldom be the harbinger of acute illness. Most commonly, it will be a false reading or a transient finding due to random variation or anxiety that requires no evaluation or treatment and can be rechecked in the future. On occasion, it will be the only or most apparent manifestation of a chronic condition or risk factor. The measurement of an elevated blood pressure leading to a diagnosis of hypertension is the classic example of the value of vital signs in such patients.

Patients Who Complain of Systemic Illness but Do Not Appear to Be Ill

Vital signs serve two additional roles in symptomatic patients who do not appear particularly ill. First, abnormalities in vital signs provide information that may suggest or support a diagnosis. The presence of elevated temperature in a patient with productive cough, shortness of breath, and localized rales and egophony supports a diagnosis of infectious pneumonia. Vital signs may also play a role in defining therapy and triage. For example, guidelines for patients with community-acquired pneumonia (Chapter 97) formally incorporate vital signs.

The second role of vital signs in the stable symptomatic patient is to provide warning that the patient is sicker than he or she appears. For example, the presence of hypotension in a well-appearing patient thought to have pyelonephritis may be an indication of sepsis or hypovolemia. For vital signs to be of use, the physician must be aware of them and must incorporate them explicitly into a thought process that considers the dangerous diagnoses associated with the abnormal vital sign. The physician then must decide whether the likelihood of each potentially dangerous diagnosis is high enough to warrant specific evaluation. Unfortunately, no quick or easy rules differentiate spurious abnormalities that can be ignored from those that should trigger additional testing or treatment. What can be said is that the well-trained physician who is aware of abnormal vital signs and is willing to contemplate a change in treatment or disposition in response to them is less likely to make mistakes.

A few specific points bear mention. First, for most vital signs, "normal" is relative. Blood pressure must be interpreted in the context of the patient. For example, a blood pressure of 88/64 mm Hg may be reasonable for an otherwise healthy, young 50-kg woman but should cause concern in a 90-kg middle-aged man. Similarly, a blood pressure of 128/80 mm Hg would be fine in a 60-year-old man but worrisome in a 34-week pregnant woman. Second, because vital signs are insensitive measures of disease, normal vital signs should not dissuade the physician from pursuing potentially critical diagnoses. For example, young, well-conditioned adults may maintain normal vital signs well into the course of shock.

Use of Vital Signs in Patients Who Appear to Be Ill

For some patients, abnormal vital signs are expected on the basis of their appearance and their symptoms. For patients in extremis, care should proceed according to established guidelines such as Advanced Cardiac Life Support (Chapter 63), Advanced Trauma Life Support, and algorithms for the treatment of shock (Chapters 107 and 108). For other ill-appearing patients, two processes must occur. In one, the physician, armed with knowledge of the differential diagnosis of each abnormal vital sign and the ability to take a thorough history and to perform an appropriate physical examination, narrows the list of potential diagnoses and decides which are of sufficient probability to warrant evaluation. Simultaneously, the physician considers the list of treatment options for all diagnoses associated with the abnormal vital sign and, before establishing a diagnosis, initiates those treatments for which the potential benefit of prompt administration exceeds potential harms. For example, antibiotics for febrile patients at risk for bacterial infection, hydrocortisone for hypotensive patients at risk for hypoadrenalism, and thiamine for hypothermic patients at risk for Wernicke's encephalopathy may improve outcome and are unlikely to cause harm even if the patient does not have the suspected condition. Although early presumptive treatment can be life-saving in selected patients, it should not be abused; physicians must avoid knee-jerk responses that can cause harm.

Differential Diagnosis and Treatment Options

Single Abnormal Vital Signs

Because vital signs can be abnormal in virtually any disease process, no differential diagnosis can be encyclopedic. The physician should focus initially on common diseases and diseases that require specific treatment. The thought process should begin with the chief complaint and history and then incorporate information about the vital signs and the remainder of the physical examination.

Multiple Abnormal Vital Signs

Patients who are acutely ill are likely to have several abnormal vital signs. Although certain patterns of abnormal vital signs predominate in specific conditions (e.g., hypotension, tachycardia, and hypothermia in profound sepsis), no pattern can be considered pathognomonic. The physician's goal is to work toward a diagnosis while simultaneously providing treatments whose benefits outweigh potential harms.

Fever is generally accompanied by tachycardia, with the general rule of thumb that the heart rate will increase by 10 beats per minute for every 1° C increase in temperature. The absence of tachycardia with fever is known as pulse-temperature dissociation and has been reported in typhoid fever (Chapter 316), legionnaires disease (Chapter 322), babesiosis (Chapter 361), Q fever (Chapter 335), infection with *Rickettsia* spp (Chapter 335), malaria (Chapter 353), leptospirosis (Chapter 331), pneumonia caused by *Chlamydia* spp (Chapter 326), and viral infections such as dengue fever (Chapter 390), yellow fever (Chapter 389), and viral hemorrhagic fevers (Chapter 389), although the predictive value of this finding is unknown.

Much can be learned by comparing the respiratory rate with pulse oximetry. Hyperventilation in the presence of high oxygen saturation suggests a central nervous system process or metabolic acidosis rather than a cardiopulmonary process. Low respiratory rates in the presence of low levels of oxygen saturation suggest central hypoventilation, which may respond to narcotic antagonists.

Hypertension and bradycardia in the obtunded or comatose patient are known as the Cushing reflex, a relatively late sign of elevated intracranial pressure. Physicians should strive to diagnose and treat this condition before the Cushing reflex develops.

Approach to Abnormalities of Specific Vital Signs

Elevated Temperature

Normal temperature is often cited as 37° C (98.6° F), but there is considerable diurnal variation and variation among individuals, so 38° C is the most commonly cited threshold for fever. Fever thought to be due to infection should be treated with antipyretics and appropriate antimicrobials (Chapter 288). The importance of early administration of antibiotics to potentially septic patients cannot be overstated (Chapters 108 and 288). Hyperthermia (temperature above 40° C) should be treated with cooling measures such as ice packs, cool misting in front of fans, cold gastric lavage, and, for medication-related syndromes, medications such as dantrolene (Chapter 109). Most hospital anesthesia departments will have a designated kit for the treatment of malignant hyperthermia (Chapters 440 and 442).

Low Temperature

The treatment of hypothermia is guided by its cause (Chapter 109). The body's temperature decreases when heat loss exceeds heat production. Every logically possible mechanism for this phenomenon has been observed. Decreased heat production can result from endocrine hypofunction (e.g., Addison's disease [Chapter 234], hypopituitarism [Chapter 231], hypothyroidism [Chapter 233]) and loss of the ability to shiver (e.g., drug-induced or neurologic paralysis or neuromuscular disorders). Malfunction of the hypothalamic regulatory system can be due to hypoglycemia (Chapter 236) and a variety of central nervous system disorders (Wernicke's encephalopathy [Chapter 425], stroke [Chapter 414], tumor [Chapter 195], and trauma [Chapter 406]). Resetting of the temperature set point can occur with sepsis. Increased heat loss can be due to exposure, behavioral and physical disorders that prevent the patient from sensing or responding to cold, skin disorders that decrease its ability to retain heat, and vasodilators (including ethanol). A careful history and physical examination should illuminate which of these possibilities is most likely.

Several considerations are worthy of emphasis. The spine of an obtunded hypothermic patient who is "found down" must be protected and evaluated because paralysis from a fall may have prevented the patient from seeking shelter and may have diminished the ability to produce heat. The physician should not forget to administer antibiotics to patients who may be septic (Chapter 108), thiamine to those who may have Wernicke's encephalopathy (Chapter 425), hydrocortisone to those who may be hypoadrenal (Chapter 234), and thyroid hormone to those who may have myxedema coma (Chapter 233). Severely hypothermic patients should be treated gently because any stimulation may trigger ventricular dysrhythmias (Chapter 109); even in the absence of pulses, cardiopulmonary resuscitation should be used only in patients with ventricular fibrillation or asystole.

Elevated Heart Rate

The rate, rhythm, and electrocardiogram differentiate sinus tachycardia from tachyarrhythmias (Chapters 62 to 65). Tachyarrhythmias can be instigated by conditions that may require specific treatment (e.g., sepsis [Chapter 108], electrolyte disorders [Chapters 118, 119, and 120], endocrine disorders [Chapter 233], and poisonings [Chapters 21 and 110]) before the arrhythmia is likely to resolve. For sinus tachycardia, treatment of the underlying cause is always paramount. Treatments may include antipyretics (for fever); anxiolytics; oral or intravenous fluids (for hypovolemia); nitrates, angiotensin-converting enzyme inhibitors, and diuretics (for heart failure and fluid overload [Chapter 59]); oxygen (for hypoxemia); α-blockers (for stimulant overdose); β-blockers (for acute coronary syndromes [Chapters 72 and 73] or thyroid storm [Chapter 233]); and anticoagulation (for pulmonary embolism [Chapter 98]). Tachycardia is often an appropriate response to a clinical condition and should not be treated routinely unless it is causing or is likely to cause secondary problems.

Low Pulse

Bradycardia can be physiologic (athletes and others with increased vagal tone), due to prescribed cardiac medications (e.g., β-blockers, calcium-channel blockers, digoxin), overdoses (e.g., cholinergics, negative inotropes), disease of the cardiac conducting system, electrolyte abnormalities (severe hyperkalemia), and inferior wall myocardial infarction (Chapters 64 and 73). Asymptomatic patients do not require immediate treatment. The goal of therapy is to produce a heart rate sufficient to perfuse the tissues and alleviate the symptoms (Chapter 63). Overdoses should be treated with specific antidotes (Chapter 110). Endocrine disorders should be treated with replacement therapy. In patients with acute coronary syndrome (Chapter 72), the goal is to restore perfusion and alleviate the ischemia. Patients with profound bradycardia or hypotension may require chronotropic drugs to increase perfusion even if they may increase myocardial oxygen demand. In normotensive patients with milder bradycardia, chronotropic agents should be used only if symptoms and ischemia cannot be resolved by other means. Atropine is the primary therapy for bradycardia; isoproterenol and cardiac pacing are reserved for those who do not respond (Chapter 63).

Elevated Blood Pressure

Elevated blood pressure does not require acute treatment in the absence of symptoms or signs of end-organ damage (Chapter 67). In patients whose blood pressure is markedly above their baseline, the history and physical examination should assess for the conditions that define "hypertensive emergency": evidence of encephalopathy, intracranial hemorrhage, ischemic stroke, heart failure, pulmonary edema, acute coronary syndrome, aortic dissection, renal failure, and preeclampsia. In the absence of these conditions, treatment should consist of restarting or adjusting the medications of patients with known hypertension and initiating a program of blood pressure checks and appropriate evaluation for those with no prior history of hypertension (Chapter 67).

The patient with a true hypertensive emergency should be treated with agents appropriate for the specific condition. Because rapid decreases in blood pressure can be as deleterious as the hypertensive state itself, intravenous agents with short half-lives, such as nitroprusside, labetalol, nitroglycerin, and esmolol, are preferred (Chapter 67).

Low Blood Pressure

Low blood pressure must be evaluated in the context of the patient's symptoms, general appearance, and physical examination findings. Treatment depends on context. The same blood pressure value may necessitate intravenous inotropic agents in one patient and no treatment in another.

In tachycardic hypotensive patients, the physician must rapidly integrate all available evidence to determine the patient's volume state, cardiac function, vascular capacitance, and primary etiology (Chapter 106). Not all patients with hypotension and tachycardia are in shock, and not all patients in shock will have hypotension and tachycardia. Patients in shock should be treated on the basis of the cause (Chapters 106 to 108).

Symptomatic hypotensive patients thought to be intravascularly volume depleted should receive intravenous fluid resuscitation with crystalloid or blood, depending on their hemoglobin level (Chapter 106). In patients with known heart disease, patients who are frail or elderly, and patients whose volume status is uncertain, small boluses of fluid (e.g., 250 mL of normal saline), each followed by reassessment, are preferred so that iatrogenic heart failure may be avoided. Inotropic support should be reserved for patients who do not respond to fluid resuscitation. High-output heart failure should be kept in mind in patients with possible thyroid storm or stimulant overdose.

Increased Respiratory Rate

Tachypnea is a normal response to hypoxemia (see later). Treatment of tachypnea in the absence of hypoxemia is directed at the underlying cause, which often is pain (Chapter 29). Anxiolytics (e.g., diazepam, 5 to 10 mg PO or IV; lorazepam, 1 to 2 mg PO, IM, or IV) or reassurance can calm patients with behavioral causes of hyperventilation. Breathing into a paper bag has been shown to be an ineffective treatment. Pulmonary embolism (Chapter 98) does not necessarily reduce the oxygen saturation or cause a low Po_2 and should always be considered in at-risk patients with unexplained tachypnea.

Decreased Respiratory Rate

Any perturbation of the respiratory center in the central nervous system can slow the respiratory drive (Chapter 86). Narcotics and other sedatives and neurologic conditions are common causes of a decreased respiratory rate. The primary treatment of apnea is mechanical ventilation (Chapter 105), but narcotic antagonists can be tried in patients with a history or physical examination findings (miosis, track marks, opiate patch) suggestive of narcotic use or abuse (Chapter 33). In nonapneic patients, mechanical ventilation is indicated for patients who are breathing too slowly to maintain an acceptable oxygen saturation and for patients who are retaining carbon dioxide in quantities sufficient to depress mental function. Patients who are unable to protect their airway should be intubated. Oxygen should be administered to all hypopneic patients who are hypoxemic (see earlier). Patients with chronic hypoventilation (Chapter 86) may have retained HCO_3^- to compensate for an elevated Pco_2 and so may depend on hypoxia to maintain respiratory drive; in these patients, overaggressive administration of oxygen can decrease the respiratory rate, increase the Pco_2, and increase obtundation (Chapter 104).

Decreased Oxygen Saturation

In hypopneic patients, initial efforts should try to increase the respiratory rate (see earlier) and tidal volume. Regardless of etiology, oxygen, in amounts adequate to restore adequate oxygen saturation (Po_2 > 60 mm Hg, oxygen saturation >90%), is the mainstay of therapy. When oxygen alone fails, noninvasive methods for improving ventilation or tracheal intubation are required (Chapter 104). Oxygen should increase the Po_2 in all patients except those who have severe right-to-left shunting (Chapter 69). Treatment of conditions

that cause hypoxemia includes antibiotics (pneumonia), bronchodilators (asthma, chronic obstructive pulmonary disease), diuretics and vasodilators (pulmonary edema), anticoagulants (pulmonary embolism), hyperbaric oxygen (carbon monoxide poisoning), methylene blue (methemoglobinemia, sulfhemoglobinemia), and transfusion (anemia).

8 STATISTICAL INTERPRETATION OF DATA

THOMAS B. NEWMAN AND CHARLES E. MCCULLOCH

ROLE AND LIMITATIONS OF STATISTICS

Much of medicine is inherently probabilistic. Not everyone with hypercholesterolemia who is treated with a statin is prevented from having a myocardial infarction, and not everyone not treated does have one, but statins reduce the *probability* of a myocardial infarction in such patients. Because so much of medicine is based on probabilities, studies must be performed on *groups* of people to estimate these probabilities. Three component tasks of statistics are (1) selecting a sample of subjects for study, (2) describing the data from that sample, and (3) drawing inferences from that sample to a larger population of interest.

SAMPLING: SELECTING SUBJECTS FOR A STUDY

The goal of research is to produce generalizable knowledge, so that measurements made by researchers on samples of individuals will eventually help draw inferences to a larger group of people than was studied. The ability to draw such inferences depends on how the subjects for the study (the sample) were selected. To understand the process of selection, it is helpful to begin by identifying the group to which the results are to be generalized and then work backward to the sample of subjects to be studied.

Target Population

The *target population* is the population to which it is hoped the results of the study will be generalizable. For example, to study the efficacy of a new drug to treat obesity, the target population might be all people with a certain level of obesity (e.g., body mass index [BMI] of ≥30 kg/m^2) who might be candidates for the drug.

Sampling

The *intended sample* is the group of people who are eligible to be in the study based on meeting *inclusion criteria,* which specify the demographic, clinical, and temporal characteristics of the intended subjects, and not meeting *exclusion criteria,* which specify the characteristics of subjects whom the investigator does not wish to study. For example, for a study of obesity, the intended sample (inclusion criteria) might be men and women 18 years or older who live in one of four metropolitan areas, who have a BMI of 30 kg/m^2 or higher, and who have failed an attempt at weight loss with a standard diet. Exclusion criteria might include an inability to speak English or Spanish, known alcohol abuse, plans to leave the area in the next 6 months, and being pregnant or planning to become pregnant in the next 6 months.

In some cases, particularly large population health surveys such as the National Health and Nutrition Examination Survey (NHANES), the intended sample is a *random* sample of the target population. A *simple random sample* is a sample in which every member of the target population has an equal chance of being selected. Simple random samples are the easiest to handle statistically but are often impractical. For example, if the target population is the entire population of the United States (as is the case for NHANES), a simple random sample would include subjects from all over the country. Getting subjects from thousands of distinct geographic areas to examination sites would be logistically difficult. An alternative, used in NHANES, is *cluster* sampling, in which investigators take a random sample of "clusters" (e.g., specific census tracts or geographic areas) and then try to study all or a simple random sample of the subjects in each cluster. Knowledge of the cluster sampling process must then be used during analysis of the study (see later) to draw inferences correctly back to the target population.

Regardless of the method used to select the intended sample, the *actual sample* will almost always differ in important ways because not all intended subjects will be willing to enroll in the study and not all who begin a study will complete it. In a study on treatment of obesity, for example, those who consent to be in the study probably differ in important, but difficult-to-quantify ways from those who do not (and may be more likely to do well with treatment). Furthermore, subjects who respond poorly to treatment may drop out, thus making the group that completes the study even less representative.

Statistical methods address only some of the issues involved in making inferences from a sample to a target population. Specifically, the vast majority of *statistical methods address only the effect of random variation on the inference from the intended sample to the target population.* Estimating the effects of differences between the intended sample and the actual sample depends on the quantities being estimated and content knowledge about whether factors associated with being in the actual sample are related to those quantities. One rule of thumb about generalizability is that *associations between variables* are more often generalizable than measurements of single variables. For instance, subjects who consent to be in a study of obesity may be more motivated than average, but this motivation would be expected to have less effect on the *difference* in weight loss between groups than on the average weight loss in either group.

DESCRIBING THE SAMPLE

Types of Variables

A key use of statistics is to describe sample data. Methods of description depend on the *type of variable* (Table 8-1). *Categorical* variables consist of named characteristics, whereas *numerical* variables describe the data with numbers. Categorical variables can be further divided into *dichotomous* variables, which can take on only two possible values (e.g., alive/dead); *nominal* variables, which can take on more than two values but have no intrinsic ordering (e.g., race); and *ordinal* variables, which have more than two values and an intrinsic ordering of the values (e.g., tumor stage). *Numerical* variables include *count* variables (e.g., the number of times a woman has been pregnant), *continuous* variables (those that have a wide range of possible values), and *time-to-event* variables (e.g., the time from initial treatment to recurrence of breast cancer). Numerical variables are also ordinal by nature and can be made binary by breaking the values into two disjointed categories (e.g., systolic blood pressure >140 mm Hg or not), and thus sometimes methods designed for ordinal or binary data are used with numerical variable types, either for freedom from restrictive assumptions or for ease of interpretation.

Univariate Statistics for Continuous Variables: The "Normal" Distribution

When describing data in a sample, it is a good idea to begin with *univariate* (one variable at a time) statistics. For continuous variables, univariate statistics typically measure *central tendency* and *variability.* The most common measures of central tendency are the *mean* (or average, i.e., the sum of the observations divided by the number of observations) and the *median* (the 50th percentile, i.e., the value that has equal numbers of observations above and below it).

One of the most commonly used measures of variability is the *standard deviation* (SD). SD is defined as the square root of the *variance,* which is calculated by subtracting each value in the sample from the mean, squaring that difference, totaling all of the squared differences, and dividing by the number of observations minus 1. Although this definition is far from intuitive, the SD has some useful mathematical properties, namely, that if the distribution of the variable is the familiar bell-shaped, *normal,* or *gaussian* distribution, about 68% of the observations will be within 1 SD of the mean, about 95% within 2 SD, and about 99.7% within 3 SD. Even when the distribution is not normal, these rules are often approximately true.

For variables that are not normally distributed, the mean and SD are not as useful for summarizing the data. In that case, the median may be a better measure of central tendency because it is not influenced by observations far below or far above the center. Similarly, the range and pairs of percentiles, such as the 25th and 75th percentiles or the 15th and 85th percentiles, will provide a better description of the spread of the data than the SD will. The 15th and 85th percentiles are particularly attractive because they correspond, in the gaussian distribution, to about −1 and +1 SD from the mean, thus making reporting of the 50th, 15th, and 85th percentiles roughly equivalent to reporting the mean and SD.

Univariate Statistics for Categorical Variables: Proportions, Rates, and Ratios

For categorical variables, the main univariate statistic is the *proportion* of subjects with each value of the variable. For dichotomous variables, only one proportion is needed (e.g., the proportion female); for nominal variables and ordinal variables with few categories, the proportion in each group can be provided. Ordinal variables with many categories can be summarized by

TABLE 8-1 TYPES OF VARIABLES AND COMMONLY USED STATISTICAL METHODS

TYPE OF OUTCOME VARIABLE	Associated Statistical Methods		
	EXAMPLES	BIVARIATE	MULTIVARIATE
Categorical (dichotomous)	Alive; readmission to the hospital within 30 days	2 × 2 table, chi-square analysis	Logistic regression
Categorical (nominal)	Race; cancer, tumor type	Chi-square analysis	Nominal logistic regression
Categorical (ordinal)	Glasgow Coma Scale	Mann-Whitney-Wilcoxon, Kruskal-Wallis	Ordinal logistic regression
Numerical (continuous)	Cholesterol; SF-36 scales*	*t* Test, analysis of variance	Linear regression
Numerical (count)	Number of times pregnant; generalized number of mental health visits in a year	Mann-Whitney-Wilcoxon, Kruskal-Wallis	Poisson regression, linear models
Time to event regression	Time to breast cancer; time to viral rebound in HIV-positive subjects	Log rank	Cox proportional hazards

*Numerical scores with many values are often treated as though they were continuous. HIV = human immunodeficiency virus; SF-36 = short-form 36-item health survey.

using proportions or by using medians and percentiles, as with continuous data that are not normally distributed.

It is worth distinguishing among *proportions, rates,* and *ratios* because these terms are often confused. *Proportions* are unitless, always between 0 and 1 inclusive, and express what fraction of the subjects have or develop a particular characteristic or outcome. Strictly speaking, *rates* have units of inverse time; they express the proportion of subjects in whom a particular characteristic or outcome develops over a specific time period. The term is frequently misused, however. For example, the term *false-positive rate* is widely used for the proportion of subjects without a disease who test positive, even though it is a proportion, not a rate. *Ratios* are the quotients of two numbers; they can range between zero and infinity. For example, the male-to-female ratio of people with a disease might be 3:1. As a rule, if a ratio can be expressed as a proportion instead (e.g., 75% male), it is more concise and easier to understand.

Incidence and Prevalence

Two terms commonly used (and misused) in medicine and public health are *incidence* and *prevalence. Incidence* describes the number of subjects who *contract* a disease *over time* divided by the population at risk. Incidence is usually expressed as a rate (e.g., 7 per 1000 per year), but it may sometimes be a proportion if the time variable is otherwise understood or clear, as in the lifetime incidence of breast cancer or the incidence of diabetes during pregnancy. *Prevalence* describes the number of subjects who *have* a disease at *one point in time* divided by the population at risk; it is always a proportion. At any point in time, the prevalence of disease depends on how many people contract it and how long it lasts: prevalence = incidence × duration.

Bivariate Statistics

Bivariate statistics summarize the relationship between two variables. In clinical research, it is often desirable to distinguish between *predictor* and *outcome variables.* Predictor variables include treatments received, demographic variables, and test results that are thought possibly to predict or cause the *outcome variable,* which is the disease or (generally bad) event or outcome that the test should predict or treatment prevent. For example, to see whether a bone mineral density measurement (the predictor) predicts time to vertebral fracture (the outcome), the choice of bivariate statistic to assess the association of outcome with predictor depends on the types of predictor and outcome variables being compared.

Dichotomous Predictor and Outcome Variables

A common and straightforward case is when both predictor and outcome variables are dichotomous, and the results can thus be summarized in a 2 × 2 table. Bivariate statistics are also called *measures of association* (Table 8-2).

TABLE 8-2 COMMONLY USED MEASURES OF ASSOCIATION FOR DICHOTOMOUS PREDICTOR AND OUTCOME VARIABLES*

PREDICTOR	Outcome		
	YES	NO	TOTAL
Yes	a	b	**a + b**
No	c	d	**c + d**
Total	**a + c**	**b + d**	**N**
Risk ratio or relative risk (RR)	a/(a + b)	c/(c + d)	
Relative risk reduction (RRR)	1 − RR		
Risk difference or absolute risk reduction (ARR)	a/(a + b) − c/(c + d)		
Number needed to treat (NNT)	1/ARR		
Odds ratio (OR)	ad/bc		

*The numbers of subjects in each of the cells are represented by a, b, c, and d. Case-control studies allow calculation of only the odds ratio.

Relative Risk

The *relative risk* or *risk ratio* (RR) is the ratio of the proportion of subjects in one group in whom the outcome develops divided by the proportion in the other group in whom it develops. It is a general (but not universal) convention to have the outcome be something bad and to have the numerator be the risk for those who have a particular factor or were exposed to an intervention. When this convention is followed, an RR greater than 1 means that exposure to the factor was bad for the patient (with respect to the outcome being studied), whereas an RR less than 1 means that it was good. That is, risk factors that cause diseases will have RR values greater than 1, and effective treatments will have an RR less than 1. For example, in the Women's Health Initiative (WHI) randomized trial, conjugated equine estrogen use was associated with an increased risk for stroke (RR = 1.37) and decreased risk for hip fracture (RR = 0.61).

Relative Risk Reduction

The *relative risk reduction* (RRR) is 1 − RR. The RRR is generally used only for effective interventions, that is, interventions in which the RR is less than 1, so the RRR is generally greater than 0. In the aforementioned WHI example, estrogen had an RR of 0.61 for hip fracture, so the RRR would be 1 − 0.61 = 0.39, or 39%. The RRR is commonly expressed as a percentage.

Absolute Risk Reduction

The *risk difference* or *absolute risk reduction* (ARR) is the difference in risk between the groups, defined as earlier. In the WHI, the risk for hip fracture was 0.11% per year with estrogen and 0.17% per year with placebo. Again, conventionally the risk is for something bad and the risk in the group of interest is subtracted from the risk in a comparison group, so the ARR will be positive for effective interventions. In this case, the ARR = 0.06% per year, or 6 in 10,000 per year.

Number Needed to Treat

The *number needed to treat* (NNT) is 1/ARR. To see why this is the case, consider the WHI placebo group and imagine treating 10,000 patients for a year. All but 17 would not have had a hip fracture anyway because the fracture rate in the placebo group was 0.17% per year, and 11 subjects would sustain a fracture despite treatment because the fracture rate in the estrogen group was 0.11% per year. Thus, with treatment of 10,000 patients for a year, 17 − 11 = 6 fractures prevented, or 1 fracture prevented for each 1667 patients treated. This calculation is equivalent to 1/0.06% per year.

Risk Difference

When the treatment *increases* the risk for a bad outcome, the difference in risk between treated and untreated patients should still be calculated, but it

is usually just called the risk difference rather than an ARR (because the "reduction" would be negative). In that case, the NNT is sometimes called the number needed to harm. This term is a bit of a misnomer. The reciprocal of the risk difference is still a number needed to treat; it is just a number needed to treat per person harmed rather than a number needed to treat per person who benefits. In the WHI, treatment with estrogens was estimated to cause about 12 additional strokes per 10,000 women per year, so the number needed to be treated for 1 year to cause a stroke was about 10,000/12, or 833.

Odds Ratio

Another commonly used measure of association is the *odds ratio* (OR). The OR is the ratio of the *odds* of the outcome in the two groups, where the definition of the odds of an outcome is $p/(1-p)$, with p being the probability of the outcome. From this definition it is apparent that when p is very small, $1-p$ will be close to 1, so $p/(1-p)$ will be close to p, and the OR will closely approximate the RR. In the WHI, the ORs for stroke (1.37) and fracture (0.61) were virtually identical to the RRs because both stroke and fracture were rare. When p is not small, however, the odds and probability will be quite different, and ORs and RRs will not be interchangeable.

Absolute versus Relative Measures

RRRs are usually more generalizable than ARRs. For example, the use of statin drugs is associated with about a 30% decrease in coronary events in a wide variety of patient populations (Chapter 217). The ARR, however, will usually vary with the baseline risk, that is, the risk for a coronary event in the absence of treatment. For high-risk men who have already had a myocardial infarction, the baseline 5-year risk might be 20%, which could be reduced to 14% with treatment, an ARR of 6%, and an NNT of about 17 for approximately 5 years. Conversely, for a 45-year-old woman with a high low-density lipoprotein cholesterol level but no history of heart disease, in whom the 5-year risk might be closer to 1%, the same RRR would give a 0.7% risk with treatment, a risk difference of 0.3% and an NNT of 333 for 5 years.

The choice of *absolute* versus *relative measures* of association depends on the use of the measure. As noted earlier, RRs are more useful as summary measures of effect because they are more often generalizable across a wide variety of populations. RRs are also more helpful for understanding causality. However, absolute risks are more important for questions about clinical decision making because they relate directly to the tradeoffs between risks and benefits—specifically, the NNT, as well as the costs and side effects that need to be balanced against potential benefits. RRRs are often used in advertising because they are generally more impressive than ARRs. Unfortunately, the distinction between relative and absolute risks may not be appreciated by clinicians, thereby leading to higher estimates of the potential benefits of treatments when RRs or RRRs are used.

Risk Ratios versus Odds Ratios

The choice between RRs and ORs is easier: RRs are preferred because they are easier to understand. Because ORs that are not equal to 1 are always farther from 1 than the corresponding RR, they may falsely inflate the perceived importance of a factor. ORs are, however, typically used in two circumstances. First, in case-control studies (Chapter 10), in which subjects with and without the disease are sampled separately, the RR cannot be calculated directly. This situation does not usually cause a problem, however, because case-control studies are generally performed to assess rare outcomes, for which the OR will closely approximate the RR. Second, in observational studies that use a type of multivariate analysis called *logistic regression* (see later), use of the OR is convenient because it is the parameter that is modeled in the analysis.

Dichotomous Predictor Variable, Continuous Outcome Variable

Many outcome variables are naturally continuous rather than dichotomous. For example, in a study of a new treatment of obesity, the outcome might be change in weight or BMI. For a new diuretic, the outcome might be change in blood pressure. For a palliative treatment, the outcome might be a quality-of-life score calculated from a multi-item questionnaire. Because of the many possible values for the score, it may be analyzed as a continuous variable. In these cases, dichotomizing the outcome leads to loss of information. Instead, the *mean difference* between the two groups is an appropriate measure of the effect size.

Most measurements have units (e.g., kg, mm Hg), so differences between groups will have the same units and be meaningless without them. If the units of measurement are familiar (e.g., kg or mm Hg), the difference between groups will be meaningful without further manipulation. For measurements in unfamiliar units, such as a score on a new quality-of-life instrument, some benchmark is useful to help judge whether the difference in groups is large or small. What is typically done in that case is to express the difference in relation to the spread of values in the study, as measured by the SD. In this case, the *standardized mean difference* (SMD) is the difference between the two means divided by the SD of the measurement. It is thus expressed as the number of SDs by which the two groups are apart. To help provide a rough feel for this difference, a 1-SD difference between means (SMD = 1) would be a 15-point difference in IQ scores, a 600-g difference in birthweight, or a 40-mg/dL difference in total cholesterol levels.

Continuous Predictor Variable

When predictor variables are continuous, the investigator can either group the values into two or more categories and calculate mean differences or SMDs between the groups as discussed earlier or use a *model* to summarize the degree to which changes in the predictor variable are associated with changes in the outcome variable. Use of a model may more compactly describe the effects of interest but involves assumptions about the way the predictor and outcome variables are related. Perhaps the simplest model is to assume a linear relationship between the outcome and predictor. For example, one could assume that the relationship between systolic blood pressure (mm Hg) and salt intake (g/day) was linear over the range studied:

$$\mathrm{SBP}_i = a + (\mathrm{b} \times \mathrm{SALT}_i) + \varepsilon_i$$

where SBP_i is the systolic blood pressure for study subject i, SALT_i is that subject's salt intake, and ε_i is an error term that the model specifies must average out to zero across all of the subjects in the study. In this model, a is a constant, the *intercept,* and the strength of the relationship between the outcome and predictor can be summarized by the slope b, which has units equal to the units of SBP divided by the units of SALT, or mm Hg per gram of salt per day in this case.

Note that without the units, such a number is meaningless. For example, if salt intake were measured in grams per week instead of grams per day, the slope would only be one seventh as large. Thus, when reading an article in which the association between two variables is summarized, it is critical to note the units of the variables. As discussed earlier, when units are unfamiliar, they are sometimes standardized by dividing by the SDs of one or both variables.

It is important to keep in mind that use of a model to summarize a relationship between two variables may not be appropriate if the model does not fit. In the preceding example, the assumption is that salt intake and blood pressure have a linear relationship, with the slope equal to 1 mm Hg/g salt per day (the approximate value for hypertensive patients). In that case, if the range of salt intake of interest is from 1 to 10 g/day, the predicted increase in blood pressure will be 1 mm Hg as a result of a 1-g/day increase in salt intake whether that increase is from 1 to 2 g/day or from 9 to 10 g/day. If the effect of a 1-g/day change in salt intake differed in subjects ingesting low- and high-salt diets, the model would not fit, and misleading conclusions could result.

When the outcome variable is dichotomous, the relationship with the continuous predictor variable is often modeled with a *logistic* model:

$$\Pr\{Y_i = 1\} = \frac{1}{1 + e^{-(a+bx_i)}}$$

where the outcome Y_i is coded 0 or 1 for study subject i, and x_i is that subject's value of the predictor variable. Once again, a is a constant, in this case related to the probability of the disease when the predictor is equal to zero, and b summarizes the strength of the association; in this case, it is the natural logarithm of the OR rather than the slope. The OR is the OR *per unit change* in the predictor variable. For example, in a study of lung cancer, an OR of 1.06 for pack years of smoking would indicate that the odds of lung cancer increase by 6% for each pack year increase in smoking.

Because the outcome variable is dichotomous, it has no units, and "standardizing" it by dividing by its SD is unnecessary and counterproductive. On the other hand, continuous predictor variables do have units, and the OR for the logistic model will be per unit change in the predictor variable or, if standardized, per SD change in the predictor variable. Re-expressing predictors in standardized or at least more sensible units is often necessary. For example, suppose 10-year mortality risk decreases by 20% (i.e., RR = 0.8) for each

increase in gross income of $10,000. The RR associated with an increase in gross income of $1 (which is what a computer program would report if the predictor were entered in dollars) would be 0.99998, apparently no effect at all because a change of $1 in gross income is negligible and associated with a negligible change in risk. To derive the coefficient associated with a $1 change, the coefficient for a $10,000 change is raised to the $^{1}/_{10,000}$ power: $0.8^{(1/10,000)} = 0.99998$.

Multivariable Statistics

In many cases, researchers are interested in the effects of multiple predictor variables on an outcome. Particularly in observational studies, in which investigators cannot assign values of a predictor variable experimentally, it will be of interest to estimate the effects of a predictor variable of interest *independent* of the effects of other variables. For example, in studying whether regular exercise decreases the risk for heart disease, investigators would realize that those who exercise may be different in many ways from those who do not and try to take differences in race, sex, age, cigarette smoking, blood pressure, and cholesterol into account. Trying to subdivide the data by race, sex, cigarette smoking status, blood pressure, and cholesterol would require a massive data set and raise the issue of multiple testing (see later). Once again, models are generally used because they enable the information about individual predictors to be summarized by using the full data set. In this way, the estimated coefficients from the model are powerful descriptive statistics that allow a sense of the data in situations in which simpler methods fail. These models are similar to those described earlier but include terms for the additional variables.

Multiple Linear Regression

The multiple linear regression model for an outcome variable Y as function or predictor variables x_1, x_2, and so forth is as follows:

$$Y_i = a + (b_1 \times x_{1i}) + (b_2 \times x_{2i}) + \ldots + (b_k \times x_{ki}) + \varepsilon_i,$$

where the subscripts *1, 2, …, k* are for the first, second, … *kth* variables of the model, and the *i* subscripts are for each individual. As before, the relationships between each of these predictor variables and the outcome variable are summarized by coefficients, or slopes, which have units of the units of *Y* divided by the units of the associated predictor. In addition, the linear combination of predictor variables adds a major simplifying constraint (and assumption) to the model: it specifies that the effects of each variable on the outcome variable are the same regardless of the values of other variables in the model. Thus, for example, if x_1 is the variable for salt intake and x_2 is a variable for sex (e.g., 0 for females and 1 for males), this model assumes that the average effect of a 1-g increase in daily salt intake on blood pressure is the same in men and women. If such is not believed to be the case, either based on previous information or from examining the data, the model should include *interaction* terms, or separate models should be used for men and women.

Multiple Logistic Regression

The logistic model expands to include multiple variables in much the same way as the linear model:

$$\Pr\{Y_i = 1\} = \frac{1}{1 + e^{-(a + b_1 x_{1i} + b_2 x_{2i} + \ldots + b_{k1} x_{ki})}}$$

Again, the additional assumption when more than one predictor is included in the model is that in the absence of included interaction terms, the effect of each variable on the odds of the outcome is the same regardless of the values of other variables in the model. Because the logistic model is multiplicative, however, the effects of different predictors on the odds of the outcome are multiplied, not added. Thus, for example, if male sex is associated with a doubling of the odds for heart disease, this doubling will occur in both smokers and nonsmokers; if smoking triples the odds, this tripling will be true in both men and women, so smoking men would be predicted to have $2 \times 3 = 6$ times higher odds of heart disease than nonsmoking women.

Recursive Partitioning

Recursive partitioning, or "*classification and regression trees,*" is a prediction method often used with dichotomous outcomes that avoids the assumptions of linearity. This technique creates prediction rules by repeatedly dividing the sample into subgroups, with each subdivision being formed by separating the sample on the value of one of the predictor variables. The optimal choice of variables and cut points may depend on the relative costs of false-positive and false-negative predictions, as set by the investigator. The end result is a set of branching questions that forms a treelike structure in which each final branch provides a yes/no prediction of the outcome. The methods of fitting the tree to data (e.g., cross-validation) help reduce overfitting (inclusion of unnecessary predictor variables), especially in cases with many potential predictors.

Proportional Hazards (Cox) Model

A multivariate model often used in studies in which subjects are monitored over time for development of the outcome is the *Cox* or *proportional hazards* model. Like the logistic model, the Cox model is used for continuous or dichotomous predictor variables, but in this case with a time-to-event outcome (e.g., time to a stroke). This approach models the *rate* at which the outcome occurs over time by taking into account the number of people still at risk at any given time. The coefficients in the Cox model are logarithms of *hazard ratios* rather than ORs, interpretable (when exponentiated) as the effect of a unit change in predictors on the *hazard* (risk in the next short time period) of the outcome developing. Like the logistic model, the Cox model is multiplicative; that is, it assumes that changes in risk factors multiply the hazard by a fixed amount regardless of the levels of other risk factors. A key feature of the Cox model and other *survival analysis* techniques is that they accommodate censored data (when the time to event is known only to exceed a certain value). For example, if the outcome is time to stroke, the study will end with many subjects who have not had a stroke, so their time to stroke is known only to exceed the time to their last follow-up visit.

INFERRING POPULATION VALUES FROM A SAMPLE

The next step after describing the data is drawing inferences from a sample to the population from which the sample was drawn. Statistics mainly quantify random error, which arises by chance because even a sample randomly selected from a population may not be exactly like the population from which it was drawn. Samples that were not randomly selected from populations may be unrepresentative because of *bias,* and statistics cannot help with this type of systematic (nonrandom) error.

Inferences from Sample Means: Standard Deviation versus Standard Error

The simplest case of inference from a sample to a population involves estimating a population mean from a sample mean. Intuitively, the larger the sample size, *N*, the more likely that the sample mean will be close to the population mean, that is, close to the mean that would be calculated if every member of the population were studied. The more variability there is within the sample, the less accurate the estimate of the population mean is likely to be. Thus, the precision with which a population mean can be estimated is related to both the size of the sample and the SD of the sample. To make inferences about a population mean from a sample mean, the *standard error of the mean* (SEM), which takes both of these factors into account, is as follows:

$$\text{SEM} = \frac{\text{SD}}{\sqrt{N}}$$

To understand the meaning of the SEM, imagine that instead of taking a single sample of *N* subjects from the population, many such samples were taken. The mean of each sample could be calculated, as could the mean of those sample means and the SD of these means. The SEM is the best estimate from a single sample of what that SD of sample means would be.

Confidence Intervals

The SEM has an interpretation pertaining to means that is parallel to the SD for individual observations. Just as about 95% of *observations* in a population are expected to be within ±1.96 SD of the mean, 95% of *sample means* are expected to be within 1.96 SEM of the population mean, thereby providing the 95% confidence interval (CI), which is the range of values for the population mean consistent with what was observed from the sample.

CIs can similarly be calculated for other quantities estimated from samples, including proportions, ORs, RRs, regression coefficients, and hazard ratios. In each case, they provide a range of values for the parameter in the population consistent with what was observed in the study in the target population.

Significance Testing and *P* Values

Many papers in the medical literature include *P* values, but the meaning of *P* values is widely misunderstood and mistaught. *P* values start with calculation of a *test statistic* from the sample that has a known distribution under certain

assumptions, most commonly the *null hypothesis,* which states that there is no association between variables. *P* values provide the answer to the question, "If the null hypothesis were true, what would be the probability of obtaining, by chance alone, a value of the test statistic this large or larger (suggesting an association between groups of this strength or stronger)?"

There are a number of common pitfalls in interpreting *P* values. The first is that because *P* values less than .05 are customarily described as being "statistically significant," the description of results with *P* values less than .05 sometimes gets shortened to "significant" when in fact the results may not be clinically significant (i.e., important) at all. A lack of congruence between clinical and statistical significance most commonly arises when studies have a large sample size and the measurement is of a continuous or frequently occurring outcome.

A second pitfall is concluding that no association exists simply because the *P* value is greater than .05. However, it is possible that a real association exists, but that it simply was not found in the study. This problem is particularly likely if the sample size is small because small studies have low *power,* defined as the probability of obtaining statistically significant results if there really is a given magnitude of difference between groups in the population. One approach to interpreting a study with a nonsignificant *P* value is to examine the power that the study had to find a difference. A better approach is to look at the 95% CI. If the 95% CI excludes all clinically significant levels of the strength of an association, the study probably had an adequate sample size to find an association if there had been one. If not, a clinically significant effect may have been missed. In "negative" studies, the use of CIs is more helpful than power analyses because CIs incorporate information from the study's results.

Finally, a common misconception about *P* values is that they indicate the probability that the null hypothesis is true (e.g., that there is no association between variables). Thus, it is not uncommon to hear or read that a *P* value less than .05 implies at least a 95% probability that the observed association is not due to chance. This statement represents a fundamental misunderstanding of *P* values. Calculation of *P* values is *based on the assumption* that the null hypothesis is true. The probability that an association is real depends not just on the probability of its occurrence under the null hypothesis but also on the probability of another basis for the association (see later)—an assessment that depends on information from outside the study, sometimes called the *prior probability* of an association (of a certain magnitude) estimated before the study results were known and requiring a different approach to statistical inference. Similarly, CIs do not take into account previous information on the probable range of the parameter being estimated.

Appropriate test statistics and methods for calculating *P* values depend on the type of variable, just as with descriptive statistics (see Table 8-1). For example, to test the hypothesis that the mean values of a continuous variable are equal in two groups, a *t* test would be used; to compare the mean values across multiple groups, analysis of variance would be used. Because there are many different ways for the null hypothesis to be false (i.e., many different ways that two variables might be associated) and many test statistics that could be calculated, there are many different ways of calculating a *P* value for the association of the same two variables in a data set, and they may not all give the same answer.

Meta-analysis

Statistical techniques for inferring population values from a sample are not restricted to samples of individuals. *Meta-analysis* is a statistical method for drawing inferences from a sample of *studies* to derive a summary estimate and confidence interval for a parameter measured by the included studies, such as a risk ratio for a treatment effect. Meta-analysis allows the formal combination of results while estimating and accommodating both the within-study and between-study variations. Meta-analysis is particularly useful when raw data from the studies are not available, as is typically the case when synthesizing information from multiple published results. For example, the previously cited estimate that a 1-g/day change in salt intake is associated with a 1-mm Hg change in blood pressure was obtained from a meta-analysis of randomized trials of low-salt diets in adults.

INFERRING CAUSALITY

In many cases, a goal of clinical research is not just to identify associations but also to determine whether they are *causal,* that is, whether the predictor causes the outcome. Thus, if people who take vitamin E live longer than those who do not, it is important to know whether it is *because* they took the vitamin or for some other reason.

Determination of causality is based on considering alternative explanations for an association between two variables and trying to exclude or confirm these alternative explanations. The alternatives to a causal relationship between predictor and outcome variables are *chance, bias, effect-cause,* and *confounding. P* values and CIs help assess the likelihood of *chance* as the basis for an association. *Bias* occurs when systematic errors in sampling or measurements can lead to distorted estimates of an association. For example, if those making measurements of the outcome variable are not blinded to values of the predictor variable, they may measure the outcome variable differently in subjects with different values of the predictor variable, thereby distorting the association between outcome and predictor.

Effect-cause is a particular problem in cross-sectional studies, in which (in contrast to longitudinal studies) all measurements are made at a single point in time, thereby precluding demonstration that the predictor variable preceded the outcome—an important part of demonstrating causality. Sometimes biology provides clear guidance about the direction of causality. For example, in a cross-sectional study relating levels of urinary cotinine (a measure of exposure to tobacco smoke) to decreases in pulmonary function, it is hard to imagine that poor pulmonary function caused people to be exposed to smoke. Conversely, sometimes inferring causality is more difficult: are people overweight because they exercise less, or do they exercise less because they are overweight (or both)?

Confounding

Confounding can occur when one or more extraneous variables is associated with both the predictor of interest and the outcome. For example, observational studies suggested that high doses of vitamin E might decrease the risk for heart disease. However, this association seems to have been largely due to confounding: people who took vitamin E were different in other ways from those who did not, including differences in factors causally related to coronary heart disease. If such factors are known and can be measured accurately, one way to reduce confounding is to *stratify* or *match* on these variables. The idea is to assemble groups of people who did and did not take vitamin E but who were similar in other ways. Multivariate analysis can accomplish the same goal—other measured variables are held constant statistically, and the effect of the variable of interest (in this case the use of vitamin E) can be examined. Multivariate analysis has the advantage that it can control simultaneously for more potentially confounding variables than can be considered with stratification or matching, but it has the disadvantage that a model must be created (see earlier), and this model may not fit the data well.

A new technique that is less dependent on model fit but still requires accurate measurements of confounding variables is the use of *propensity scores.* Propensity scores are used to assemble comparable groups in the same way as stratification or matching, but in this case the comparability is achieved on the basis of the *propensity* to be exposed to or be treated with the predictor variable of primary interest.

A major limitation of these methods of controlling for confounding is that the confounders must be known to the investigators and accurately measured. In the case of vitamin E, apparent favorable effects persisted after controlling for known confounding variables. It is for this reason that randomized trials provide the strongest evidence for causality. If the predictor variable of interest can be randomly assigned, confounding variables, both known and unknown, should be approximately equally distributed between the subjects who are and are not exposed to the predictor variable, and it is reasonable to infer that any significant differences in outcome that remain in these now comparable groups would be due to differences in the predictor variable of interest. In the case of vitamin E, a recent meta-analysis of randomized trials found no benefit whatsoever and in fact suggested harm from high doses.

OTHER COMMON STATISTICAL PITFALLS

Missing Data

Research on human subjects is challenging. People drop out of studies, refuse to answer questions, miss study visits, and die of diseases that are not being studied directly in the protocol. Consequently, missing or incomplete data are a fact of medical research. When the fact that data are missing is unrelated to the outcome being studied (which might be true, for example, if the files storing the data got partially corrupted), analyses using only the data present (sometimes called a complete case analysis) are unlikely to be misleading. Unfortunately, such is rarely the case. Subjects refusing to divulge family income probably have atypical values, patients not coming for scheduled

visits in a study of depression may be more or less depressed, and patients in an osteoporosis study who die of heart disease probably differ in many ways from those who do not.

Whenever a sizable fraction of the data is missing (certainly if it is above 10 or 15%), there is the danger of substantial bias from an analysis that uses only the complete data. This is the gap noted earlier between the intended and actual samples. Any study with substantial missing data should be clear about how many missing data there were and what was done to assess or alleviate the impact; otherwise, the critical consumer of such information should be suspicious. In a randomized trial, the general rule is that the primary analysis should include all subjects who were randomized, regardless of whether they followed the study protocol, in an *intention-to-treat* analysis.

Clustered or Hierarchical Data

Data are often collected in a clustered (also called hierarchical) manner; for example, NHANES used a cluster sample survey, and a study of patient outcomes might be conducted at five hospitals, each with multiple admission teams. The cluster sample or the clustering of patients within teams within hospitals leads to correlated data. Said another way, and other things being equal, data collected on the same patient, by the same admission team, or in the same cluster are likely to be more similar than data from different patients, teams, or clusters. Failure to use statistical methods that accommodate correlated data can seriously misstate standard errors, widths of CIs, and *P* values. Unfortunately, standard errors, CIs, and *P* values can be estimated to be too small or too large when using a naïve analysis. Statistical methods for dealing with correlated data include *generalized estimating equations* and the use of *robust standard errors* and *frailty models* (for time-to-event data). Studies with obvious hierarchical structure that fail to use such methods may be in serious error.

Multiple Testing

The "multiple testing" or "multiple comparisons" issue refers to the idea that if multiple hypothesis tests are conducted, each at a significance level of .05, the chance that at least one of them will achieve a *P* value of less than .05 is considerably larger than .05, even when all the null hypotheses are true. For example, when comparing the mean value of a continuous variable across many different groups, analysis of variance is a time-tested method of performing an overall test of equality and avoiding making a large number of pairwise comparisons.

Because most medical studies collect data on a large number of variables, performing a test on each one may generate a number of false-positive results. The risk for falsely positive results is especially high with genomic studies, in which a researcher may test a million single-nucleotide polymorphisms for association with a disease.

A typical method for dealing with the problem of multiple testing is the *Bonferroni correction,* which specifies that the *P* value at which the null hypothesis will be rejected (e.g., .05) should be *divided by the number of tests performed*. Although simple to use, a problem with this approach is that it is often difficult to decide how many tests make up the "universe" of tests. Some newer methods for genomic studies involve controlling the *false discovery rate.*

Studies with many listed or apparent outcomes or predictors (or both) are subject to inflation of the error rate to well above the nominal .05. Automated stepwise regression methods for choosing predictors in regression models typically *do not* alleviate and may exacerbate this problem. If no adjustment or method for dealing with multiple comparisons is used, the chance for a false-positive result in a study should be kept in mind.

USING DATA FOR CLINICAL DECISIONS

THOMAS H. LEE

Key functions in the professional lives of all physicians are the collection and analysis of clinical data. Decisions must be made on the basis of these data, including which therapeutic strategy is most appropriate for the patient and whether further information should be gathered before the best strategy can be chosen. This decision-making process is a blend of science and art in which the physician must synthesize a variety of concerns, including the patient's most likely outcome with various management strategies, the patient's worst possible outcome, and the patient's preferences among these strategies.

Only rarely does the physician enjoy true certainty regarding any of these issues, so a natural inclination for physicians is to seek as much information as possible before making a decision. This approach ignores the dangers inherent in the collection of information. Some of these dangers are immediate, such as the risk of cerebrovascular accident associated with coronary angiography. Other dangers are delayed, such as the risk of a malignancy due to radiation exposure from diagnostic tests.

An additional concern is the cost of information gathering, including the direct costs of the tests themselves and the indirect costs that flow from decisions made on the basis of the test results. Substantial data demonstrate marked variation in use of tests among physicians located in different regions and even within the same group practice. Standards of medical professionalism endorse the need for physicians to exert their influence to minimize inefficiency, but this challenge grows increasingly complex as medical progress leads to proliferation of alternative testing strategies.

For the physician, there are three key questions in this sequence: Should I order a test to improve my assessment of diagnosis or prognosis? Which test is best? Which therapeutic strategy is most appropriate for this patient?

SHOULD I ORDER A TEST?

The decision of whether to order a test depends on the physician's and the patient's willingness to pursue a management strategy with the current degree of uncertainty. This decision is influenced by several factors, including the patient's attitudes toward diagnostic and therapeutic interventions (e.g., a patient with claustrophobia might prefer an ultrasound to magnetic resonance imaging) and the information provided by the test itself. The personal tolerance of the patient and physician for uncertainty also frequently influences test-ordering approaches. A decision to watch and wait rather than to obtain a specific test also should be considered an information-gathering alternative because the information obtained while a patient is being observed often reduces uncertainty about the diagnosis and outcome. In other words, the "test of time" should be recognized as one of the most useful tests available when this tactic does not seem inappropriately risky.

Most tests do not provide a definitive answer about diagnosis or prognosis but instead reduce uncertainty. Accordingly, the impact of information from tests often is expressed as *probabilities* (Table 9-1). A probability of 1.0 implies that an event is certain to occur, whereas a probability of 0 implies that the event is impossible. When all the possible events for a patient are assigned probabilities, these estimates should sum to 1.0.

It is often useful to use *odds* to quantify uncertainty instead of probability. Odds of 1:2 suggest that the likelihood of an event is only half the likelihood that the event will not occur. The relationship between odds and probability is expressed in the following formula:

$$\text{Odds} = P/(1-P)$$

where P is the probability of an event.

TABLE 9-1 KEY DEFINITIONS*

Probability	A number between 0 and 1 that expresses an estimate of the likelihood of an event
Odds	The ratio of [the probability of an event] to [the probability of the event not occurring]
TEST PERFORMANCE CHARACTERISTICS	
Sensitivity	Percentage of patients with disease who have an abnormal test result
Specificity	Percentage of patients without disease who have a normal test result
Positive predictive value	Percentage of patients with an abnormal test result who have disease
Negative predictive value	Percentage of patients with a normal test result who do not have disease
BAYESIAN ANALYSIS	
Pretest (or prior) probability	The probability of a disease before the information is acquired
Post-test (or posterior) probability	The probability of a disease after new information is acquired
Pretest (or prior) odds	(Pretest probability of disease)/(1 – pretest probability of disease)
Likelihood ratio	(Probability of result in diseased persons)/(probability of result in nondiseased persons)

**Disease* can mean a condition, such as coronary artery disease, or an outcome, such as postoperative cardiac complications.

Performance Characteristics

Sensitivity and *specificity* are key terms for the description of test performance. These parameters describe the test and are in theory true regardless of the population of patients to which the test is applied. Research studies that describe test performance often are based, however, on highly selected populations of patients; test performance may deteriorate when tests are applied in clinical practice. The result of a test for coronary artery disease, such as an electron beam computed tomography scan, rarely may be abnormal if it is evaluated in a low-risk population, such as high-school students. False-positive abnormal results secondary to coronary calcification in the absence of obstructive coronary disease are common when the test is performed in middle-aged and elderly people.

Although researchers are interested in the performance of tests, the true focus of medical decision making is the patient. Physicians are more interested in the implications of a test result on the probability that a patient has a specific disease or outcome, that is, the predictive values of abnormal or normal test results. These predictive values are extremely sensitive to the population from which they are derived (Table 9-2; see also Table 9-1). An abnormal lung scan result in an asymptomatic patient has a much lower positive predictive value than that same test result in a patient with dyspnea and a diminished oxygen saturation. Bayes' theorem (see later) provides a framework for analyzing the interaction between test results and a patient's pretest probability of a disease.

As useful as the performance characteristics may be, they are limited by the fact that few tests truly provide dichotomous (i.e., positive or negative) test results. Tests such as exercise tests have several parameters (e.g., ST segment deviation, exercise duration, hemodynamic response) that provide insight into the patient's condition, and the normal range for many blood tests (e.g., prostate-specific antigen) varies markedly according to the age of the tested population and one's willingness to "miss" patients with disease. Tests that require human interpretation (e.g., radiologic studies) are particularly subject to variability in the reported results.

Bayes' Theorem

The impact of a test result on a patient's probability of disease was first quantified by Bayes, an 18th-century English clergyman who developed a formula that describes the probability of disease in the presence of an abnormal test result. The classic presentation of Bayes' theorem is complex and difficult to use. A simpler form of this theorem is known as the *odds ratio* form, which describes the impact of a test result on the pretest odds (see Table 9-1) of a diagnosis or outcome for a specific patient.

To calculate the post-test odds of disease, the pretest odds are multiplied by the *likelihood ratio* (LR) for a specific test result. The mathematical presentation of this form of Bayes' theorem is as follows:

$$\text{Post-test odds} = (\text{Pretest odds}) \times (\text{LR})$$

The LR is the probability of a particular test result in patients with the disease divided by the probability of that same test result in patients without disease. In other words, the LR is the test result's sensitivity divided by the false-positive rate. A test of no value (e.g., flipping a coin and calling "heads" an abnormal result) would have an LR of 1.0 because half of patients with disease would have abnormal test results, as would half of patients without disease. This test would have no impact on a patient's odds of disease. The further an LR is above 1.0, the more that test result raises a patient's probability of disease. For LRs less than 1.0, the closer the LR is to 0, the more it lowers a patient's probability of disease.

When it is displayed graphically (Fig. 9-1), a test of no value (*dotted line*) does not change the pretest probability, whereas an abnormal or normal result from a useful test moves the probability up or down. For a patient with a high pretest probability of disease, an abnormal test result changes the patient's probability only slightly, but a normal test result leads to a marked reduction in the probability of disease. Similarly, for a patient with a low pretest probability of disease, a normal test result has little impact, but an abnormal test result markedly raises the probability of disease.

Consider how various exercise test results influence a patient's probability of coronary disease (see Table 9-2). For a patient whose clinical history, physical examination, and electrocardiographic findings suggest a 50% probability of disease, the pretest odds of disease are 1.0. LRs for various test results are developed by pooling data from published literature. The sensitivity of an exercise test with any amount of ST segment changes is the rate of such test results in patients with coronary disease, and the specificity is the percentage of patients without coronary disease who do *not* have this test result. The LR for no ST change is less than 1, whereas the LRs for patients with ST changes are greater than 1 (see Table 9-2). Therefore, when the LRs for various test results are multiplied by the pretest odds to calculate post-test odds, the odds decrease for patients without ST segment changes but increase for patients with 1 or 2 mm of ST segment change. Post-test odds can be converted to post-test probabilities according to the following formula:

$$\text{Probability} = \text{Odds}/(1 + \text{odds})$$

The calculations quantify how the absence of ST segment changes reduces a patient's probability of disease, whereas ST segment depression raises the probability of disease.

This form of Bayes' theorem is useful for showing how the post-test probability of disease is influenced by the patient's pretest probability of disease.

TABLE 9-2 EXAMPLE OF ODDS RATIO FORM OF BAYES' THEOREM

Question: What is the probability of coronary disease for a patient with a 50% pretest probability of coronary disease who undergoes an exercise test if that patient develops (a) no ST segment changes, (b) 1 mm of ST segment depression, or (c) 2 mm of ST segment depression?

Step 1. Calculate the pretest odds of disease:

$$P/(1-P) = 0.5/(1-0.5) = 0.5/0.5 = 1$$

Step 2. Calculate the likelihood ratios for the various test results, using the formula LR = sensitivity/(1 − specificity). (Data from pooled literature.)

TEST RESULT	SENSITIVITY	SPECIFICITY	LIKELIHOOD RATIO
No ST segment changes	0.34	0.15	0.4
1-mm ST segment depression	0.66	0.85	4.4
2-mm ST segment depression	0.33	0.97	11

Step 3. Calculate the post-test odds of disease and convert those odds to post-test probabilities:

TEST RESULT	PRETEST ODDS	LIKELIHOOD RATIO	POST-TEST ODDS	POST-TEST PROBABILITY
No ST segment changes	1	0.4	0.4	0.29
1-mm ST segment depression	1	4.4	4.4	0.81
2-mm ST segment depression	1	11	11	0.92

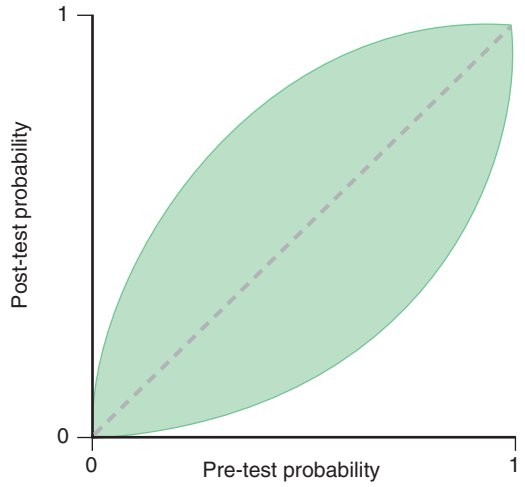

FIGURE 9-1. Impact of various test results on the patient's probability of disease. The x axis depicts a patient's probability of disease before a test. If the test is of no value, the post-test probability *(dotted line)* is no different from the pretest probability. An abnormal test result raises the post-test probability of disease, as depicted by the concave downward arc, whereas a normal test result lowers the probability.

TABLE 9-3 PRINCIPLES OF TEST ORDERING AND INTERPRETATION

The interpretation of test results depends on what is already known about the patient.
No test is perfect; clinicians should be familiar with their diagnostic performance (see Table 9-1) and never believe that a test "forces" them to pursue a specific management strategy.
Tests should be ordered if they may provide *additional* information beyond that already available.
Tests should be ordered if there is a reasonable chance that the data will influence the patient's care.
Two tests that provide similar information should not be ordered.
In choosing between two tests that provide similar data, use the test that has lower costs and/or causes less discomfort and inconvenience to the patient.
Clinicians should seek all of the information provided by a test, not just an abnormal or normal result.
The cost-effectiveness of strategies using noninvasive tests should be considered in a manner similar to that of therapeutic strategies.

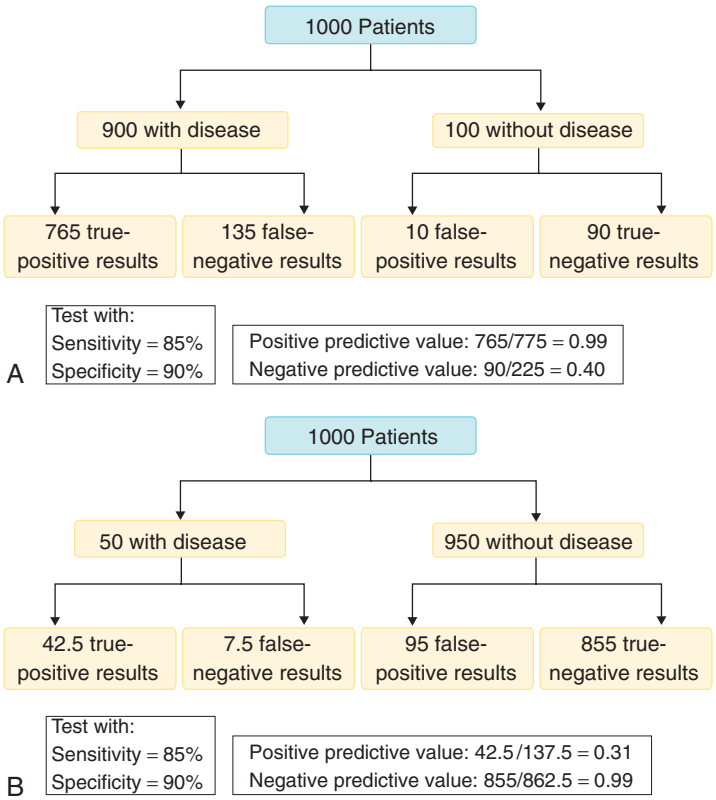

FIGURE 9-2. Interpretation of test results in high-risk and low-risk patients. A, High-risk population (90% prevalence of disease). **B,** Low-risk population (5% prevalence of disease).

If a patient's clinical data suggest a *probability* of coronary disease of only 0.1, the *pretest odds* of disease would be only 0.11. For such a low-risk patient, an exercise test with no ST segment changes would lead to post-test probability of coronary disease of 4%, whereas 1- or 2-mm ST segment changes would lead to a post-test probability of disease of 33 or 55%.

Even if clinicians rarely perform the calculations that are described in Bayes' theorem, there are important lessons from this theorem that are relevant to principles of test ordering (Table 9-3). The most crucial of these lessons is that the interpretation of test results must incorporate information about the patient. An abnormal test result in a low-risk patient may not be a true indicator of disease. Similarly, a normal test result in a high-risk patient should not be taken as evidence that disease is not present.

Figure 9-2 provides an example of the post-test probabilities for positive and negative results for a test with a sensitivity of 85% and a specificity of 90% (e.g., radionuclide scintigraphy for diagnosis of coronary artery disease). In a high-risk population with a 90% prevalence of disease, the positive predictive value of an abnormal result is 0.99 compared with 0.31 for the same test result obtained in a low-risk population with a 5% prevalence of disease. Similarly, the negative predictive value of a normal test result is greater in the low-risk population than in the high-risk population.

Multiple Testing

Clinicians frequently obtain more than one test aimed at addressing the same issue and at times are confronted with conflicting results. If these tests are truly independent (i.e., the tests do not have the same basis in pathophysiology), it may be appropriate to use the post-test probability obtained through performance of one test as the pretest probability for the analysis of the impact of the second test result.

If the tests are not independent, this strategy for interpretation of serial test results can be misleading. Suppose a patient with chronic obstructive pulmonary disease and a history vaguely suggestive of pulmonary embolism is found to have an abnormal lung ventilation-perfusion scan. Obtaining that same test result over and over would not raise that patient's probability of pulmonary embolism higher and higher. In this extreme case, the tests are identical; serial testing adds no information. More commonly, clinicians are faced with results from tests with related but not identical bases in pathophysiology, such as ventilation-perfusion scintigraphy and pulmonary angiography.

Regardless of whether tests are independent, the performance of multiple tests increases the likelihood that an abnormal test result will be obtained in a patient without disease. If a chemistry battery includes 20 tests and the normal range for each test has been developed to include 95% of healthy individuals, the chance that a healthy patient will have a normal result for any specific test is 0.95. However, the probability that all 20 tests will be normal is $(0.95)^{20}$, or 0.36. Most healthy people can be expected to have at least one abnormal result. Unless screening test profiles are used thoughtfully, false-positive results can subject patients to unnecessary tests and procedures.

Threshold Approach to Decision Making

Even if a test provides information, that information may not change management for an individual patient. Lumbar spine radiographs of a patient who is not willing to undergo surgery may reveal the severity of disease but expose the patient to needless radiation. Similarly, a test that merely confirms a diagnosis that already is recognized is a waste of resources (see Table 9-3).

Before ordering a test, clinicians should consider whether that test result could change the choice of management strategies. This approach is called the *threshold approach to medical decision making*, and it requires the physician to be able to estimate the threshold probability at which one strategy will be chosen over another. The management of a clinically stable patient with a high probability of coronary disease might not be changed by any of the post-test probabilities shown in Table 9-2. If that patient had no ST segment changes, the post-test probability of 0.29 still would be too high for a clinician to consider that patient free of disease. An abnormal test result that strengthened the diagnosis of coronary disease might not change management unless it suggested a greater severity of disease that might warrant another management strategy.

Testing for Peace of Mind

Physicians frequently order tests even when there is little chance that the outcomes will provide qualitatively new insights into a patient's diagnosis or prognosis or alter a patient's management. In such cases, the cited goal for testing may be to improve a patient's peace of mind. Although a decrease in uncertainty can improve quality of life for many patients, individuals with hypochondriasis and somatization disorders rarely obtain comfort from normal test results; instead, their complaints shift to a new organ system, and their demands focus on other tests. For such patients, management strategies using frequent visits and cognitive tactics are recommended.

WHICH TEST IS BEST?

If the clinician decided that more information is needed to reduce uncertainty, and if it appears possible that tests might lead to a change in management strategies, the question arises as to which test is most appropriate. Note that just because guideline-development committees have concluded that a specific test is "appropriate" in given clinical context, this does not mean that this test is the *most* appropriate option. Several factors influence the choice among diagnostic strategies, including patients' preferences, the costs and risks associated with the tests, and the diagnostic performance of alternative tests.

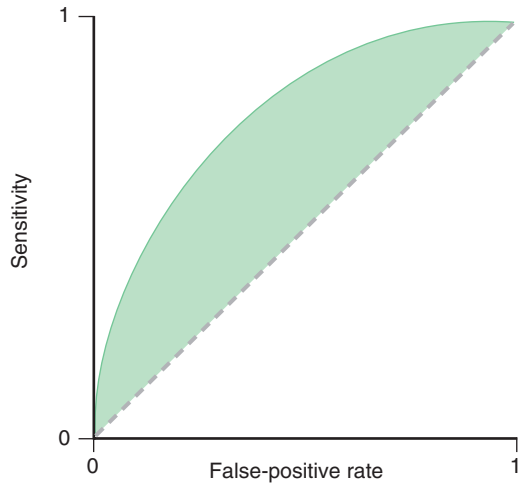

FIGURE 9-3. Receiver operating characteristic curve. The points on the curve reflect the sensitivity and false-positive (1 – specificity) rates of a test at various thresholds. As the threshold is changed to yield greater sensitivity for detecting the outcome of interest, the false-positive rate rises. The better the test, the closer the curve comes to the upper left corner. A test of no value (e.g., flipping a coin) would lead to a curve with the course of the *dotted line.* The area under the curve is used often to compare alternative testing strategies.

Diagnostic performance of a test often is summarized in terms of sensitivity and specificity, but as shown in the example in Table 9-2, these parameters depend on which threshold (e.g., 1 vs. 2 mm of ST segment change) is used. A low threshold for calling a test result abnormal might lead to excellent sensitivity for detecting disease, but at the expense of a high false-positive rate. Conversely, a threshold that led to few false-positive results might cause a clinician to miss many cases of true disease.

The receiver operating characteristic (ROC) curve is a graphic form of describing this tradeoff and providing a method for comparing test performance (Fig. 9-3). Each point on the ROC curve describes the sensitivity and the false-positive rate for a different threshold for abnormality for a test. A test of no value would lead to an ROC curve with the course of the dotted line, whereas a misleading test would be described by a curve that was concave upward (not shown).

The more accurate the test, the closer its ROC curve comes to the upper left corner of the graph, which would indicate a test threshold that has excellent sensitivity and a low false-positive rate. The closer an ROC curve comes to the upper left corner, the greater the area under the curve. The area under ROC curves can be used to compare the information provided by two tests.

Even if one test is superior to another as shown by a greater area under its ROC curve, the question still remains as to what value of that test should be considered abnormal. The choice of threshold depends on the purpose of testing and on the consequences of a false-positive or false-negative diagnosis. If the goal is to screen the population for a disease that is potentially fatal and potentially curable, a threshold with excellent sensitivity is appropriate even if it leads to frequent false-positive results. In contrast, if a test is used to confirm a diagnosis that is likely to be treated with a high-risk invasive procedure, a threshold with high specificity is preferred. Only 1 mm of ST segment depression might be the appropriate threshold when exercise electrocardiography is used to evaluate the possibility of coronary disease in a patient with chest pain. If the question is whether to perform coronary angiography in a patient with stable angina in search of severe coronary disease that might benefit from revascularization, a threshold of 2 mm or more would be more appropriate.

CHOOSING A STRATEGY

Physicians and patients ultimately must use clinical information to make decisions. These choices usually are made after consideration of a variety of factors, including information from the clinical evaluation, patients' preferences, and expected outcomes with various management strategies. Insight into the impact of these considerations can be improved through the performance of decision analysis (Table 9-4).

The first step in a decision analysis is to define the problem clearly; this step often requires writing out a statement of the issue so that it can be scrutinized for any ambiguity. After the problem is defined, the next step is to define the alternative strategies.

TABLE 9-4 STEPS IN PERFORMANCE OF DECISION ANALYSIS

Frame the question.
Create the decision tree.
Identify the alternative strategies.
List the possible outcomes for each of the alternative strategies.
Describe the sequence of events as a series of decision nodes and chance nodes.
Choose a time horizon for the analysis.
Determine the probability for each chance outcome.
Assign a value to each outcome.
Calculate the expected utility for each strategy.
Perform sensitivity analysis.

Consider the question of which test is most appropriate to screen patients for breast cancer: mammography with or without breast magnetic resonance imaging—a newer technology that is highly sensitive for detecting breast cancer but is more costly and less specific. The expected outcomes for these strategies depend on each test's sensitivity and specificity for detecting breast cancer, which is influenced in turn by other factors, such as the frequency with which the test is performed. Patients' outcomes also are influenced by their underlying risk for breast cancer and the likelihood that earlier detection of tumors reduces the risk for death.

Each of these variables must be known or estimated for calculations to be made of each strategy's predicted life expectancy and direct medical costs. These outcomes differ for patients according to age, medical history, family history, and presence or absence of genetic markers such as *BRCA* mutations. Optimal strategies for an elderly patient with a short life expectancy and low clinical risk of cancer are unlikely to be the same as for a younger patient with inherited mutations of the *BRCA1* or *BRCA2* gene, indicating a cumulative lifetime risk of breast cancer of 50 to 85% (Chapter 204).

The credibility of the decision analysis depends on the credibility of these estimates. Published reports often do not provide information on the outcomes of interest for specific subsets of patients, or there may not have been sufficient statistical power within subsets of patients for the findings to be statistically significant. Randomized trial data are relevant to the populations included in the trial; the extension of the findings to other genders, races, and age groups requires assumptions by individuals performing the analysis. For many issues, expert opinion must be used to derive a reasonable estimate of the outcome.

For many diseases, the potential outcomes are more complex than perfect health or death. With chronic diseases, patients may live many years in a condition somewhere between these two, and the goal of medical interventions may be to improve quality of life rather than to extend survival. The value of life in imperfect health must be reflected in decision analyses. These values by convention are expressed on a scale of 0 to 100, where 0 indicates the worst outcome and 100 indicates the best outcome.

Life-expectancy and quality-of-life estimates are combined in many decision analyses to calculate *quality-adjusted life years.* A strategy that leads to a 10-year life expectancy with such severe disability that utility of the state of health is only half that of perfect health would have a quality-adjusted life expectancy of 5 years. With such adjustments to life-expectancy data, the impact of interventions that improve quality of life but do not extend life can be compared with interventions that extend life but do not improve its quality or perhaps even worsen it.

After the value and the probability of the various outcomes have been estimated, the expected utility of each strategy can be calculated. In comparing the different strategies available at a decision node, the analysis generally selects the option with the highest expected utility. At chance nodes, the expected utility is the weighted average of the utility of the various possible branches.

After the analysis has been performed with the baseline assumptions, *sensitivity analyses* should be performed in which these assumptions are varied over a reasonable range. These analyses can reveal which assumptions have the most influence over the conclusions and identify threshold probabilities at which the conclusions would change. For example, the threshold at which breast magnetic resonance imaging should be added to mammography is likely to be influenced by the cost of the magnetic resonance imaging and the accuracy of the radiologists who interpret the images.

Cost-Benefit and Cost-Effectiveness Analyses

For clinicians and health care policymakers, the choices that must be addressed go beyond the choices within any single decision analysis. Because resources available for health care are limited, policymakers may have to choose among many competing "investments" in health. Although such decisions frequently are made on the basis of political considerations, cost-benefit and cost-effectiveness analyses can be informative in making the choices.

The methodology of these techniques is similar to that of decision analysis except that costs for the various possible outcomes and strategies also are calculated. *Discounting* is used to adjust the value of future benefits and costs because resources saved or spent currently are worth more than resources saved or expended in the future. In *cost-benefit* analyses, all benefits are expressed in terms of economic impact. Extensions in life expectancy are translated into dollars by estimating societal worth or economic productivity.

Because of the ethical discomfort associated with expressing health benefits in financial terms, *cost-effectiveness* analyses are used more commonly than cost-benefit analyses. In these analyses, the ratio of costs to health benefits is calculated; one frequently used method for evaluating a strategy is calculation of cost per quality-adjusted life year. These estimates can be used to compare strategies and to identify settings in which strategies that may be more expensive but more effective (e.g., coronary angiography) may "purchase" quality-adjusted life years at a lower cost than less aggressive but less effective strategies (e.g., use of positron emission tomography scanning to diagnose coronary disease) (Table 9-5).

Cost-effectiveness analyses can provide important insights into the relative attractiveness of different management strategies and can help guide policymakers in decisions about which technologies to make available on a routine basis. No medical intervention can have an attractive cost-effectiveness if its effectiveness has not been proved. The cost-effectiveness of an intervention depends heavily on the population of patients in which it is applied. An

TABLE 9-5 ESTIMATED COST-EFFECTIVENESS OF COMMON HEALTH INTERVENTIONS

DISEASE CATEGORY	INTERVENTION VS. COMPARATOR IN TARGET POPULATION	COST PER QUALITY-ADJUSTED LIFE YEAR*
Circulatory	Coronary angiography vs. positron emission tomography (PET) in 55-year-old women with chest pain and risk factors that put them at intermediate pretest probability (25-75%) of coronary artery disease	Cost saving
	Angiography vs. exercise electrocardiography (ECG) in patients with no history of myocardial infarction presenting with mild chest pain (typical angina) who are able to undergo an exercise stress test	$47,000
	Exercise single-photon emission computed tomography (SPECT) vs. exercise ECG in patients with no history of myocardial infarction presenting with mild chest pain (typical angina) who are able to undergo an exercise stress test.	$52,000
	Angiography vs. exercise ECG in patients with no history of myocardial infarction presenting with mild chest pain (atypical angina) who are able to undergo an exercise stress test	$89,000
	In patients after a first stroke or transient ischemic attack, patients with heart disease receive transesophageal echocardiography and all others receive standard medical treatment vs. all receive standard medical treatment.	$240,000
	High-dose statin therapy vs. conventional-dose statin therapy in 60-year-old cohorts with acute coronary syndromes (ACS)	$14,000
	Prophylactic implantation of an implantable-cardioverter defibrillator (ICD) vs. control therapy in patients who are at risk for sudden death due to left ventricular systolic dysfunction—Sudden Cardiac Death in Heart Failure Trial (SCD HeFT) population (https://research.tufts-nemc.org/cear/search/detail.aspx?ArticleId=2005-01-01184&id=2005-01-01184-08C)	$77,000
	Cardiac resynchronization therapy (CRT-P) plus medical therapy vs. medical therapy in a 60-year-old patient with heart failure and cardiac dyssynchrony with moderate or severe symptoms (https://research.tufts-nemc.org/cear/search/detail.aspx?ArticleId=2007-01-02351&id=2007-01-02351-13C)	$9,900
Endocrine	Thyroid-stimulating hormone (TSH) screening vs. no TSH screening in women undergoing 5-year periodic health examinations, beginning at 35 years old	$13,000
	Annual diabetic retinopathy screening vs. no screening; diabetic patients receive routine medical care until they become blind in patients diagnosed with type 2 diabetes, aged 30 years or older, undergoing eye screening (https://research.tufts-nemc.org/cear/search/detail.aspx?ArticleId=2008-01-03569&id=2008-01-03569-01C)	Cost saving
	Intensive lifestyle intervention vs. usual care in 60-year-old cohort with impaired glucose tolerance	Cost saving
	Self-monitoring of blood glucose (SMBG) vs. no SMBG in patients with type 2 diabetes receiving insulin only (https://research.tufts-nemc.org/cear/search/detail.aspx?ArticleId=2006-01-02649&id=2006-01-02649-03C)	$9600
	Intensive glucose control, therapies designed to produce HbA1c (A1C) levels of 7.2% vs. conventional glucose control, therapies designed to produce HbA1c (A1C) levels of 10% in patients with new-onset type 2 diabetes at 60-65 years of age	$200,000
Digestive system	Endoscopic surveillance strategy vs. no therapy in man who has endoscopic biopsy-proven Barrett's esophagus—age 55 years	$150,000
	One-time colonoscopic screening for colorectal cancer at age 60-64 years old vs. no screening in men >40 years old	Cost saving
Infectious	One-time rapid HIV infection screening vs. no screening in U.S. communities with low to moderate HIV prevalence (0.05% to 1.0%) and annual incidence (0.0084% to 0.12%)	$35,000
	Treating patients with peginterferon alfa-2b plus ribavirin vs. no treatment in 55-year-old male naïve patients with genotypes 1, 2, and 3 chronic hepatitis C virus (HCV) infection	Cost saving
	Provision of influenza vaccine vs. no provision of service (no vaccine) in U.S. population age 50 years and older	$7,300
Injury	Driver air bag vs. no air bags in driving population (and passengers)	$36,000
	Dual air bag vs. driver air bag in driving population (and passengers)	$91,000
Obstetrics	Elective repeat cesarean section vs. vaginal birth (trial of labor) in 30-year-old patients who have had a previous low transverse cesarean delivery	$140,000
	Elective cesarean delivery vs. vaginal delivery in 25-year-old HIV-infected pregnant women with detectable HIV RNA	Cost saving
Oncology	Adjuvant chemotherapy plus trastuzumab vs. chemotherapy alone in patients with *HER2*-positive early breast cancer, from the U.S. health care system	$21,000
	MRI vs. mammography in women aged 40-49 years with *BRCA1* mutation	$16,000

*In 2008 U.S. dollars.
HIV = human immunodeficiency virus; RNA = ribonucleic acid; TSH = thyroid-stimulating hormone.

inexpensive intervention would have a poor cost-effectiveness ratio if it were used in a low-risk population unlikely to benefit from it. In contrast, an expensive technology can have an attractive cost-effectiveness ratio if it is used in patients with a high probability of benefiting from it. Table 9-5 shows cost-effectiveness estimates from published literature for some common medical and nonmedical interventions. Such estimates should be used only with understanding of the population for which they are relevant.

MEASURING HEALTH AND HEALTH CARE

STEPHAN D. FIHN

The increasing emphasis on measuring and improving the quality of health care in the United States and elsewhere is based on several fundamental concerns. First, there is clear evidence that the health care system in the United States does not provide the highest quality of care possible. In one study, approximately 4600 randomly selected adults from 12 U.S. cities received recommended preventive, acute, or chronic care only slightly more than half the time. Second, substantial disparities in health care and outcomes persist, with women (Chapter 245), the poor (Chapter 5), and ethnic minorities (Chapter 4) typically faring less well than others. Third, there is growing concern that health care sometimes causes harm, as reflected by statistics indicating that 1 in 6.5 hospitalizations is complicated by a mistake in administering or prescribing medication, that 1 in 20 outpatient prescriptions is wrong, or that inpatient errors may cause as many as 44,000 to 98,000 deaths annually (Chapter 11). Fourth, health care is extraordinarily expensive, with an annual aggregate expenditure of more than $2 trillion (nearly $7500 per resident) that consumes nearly 17% of the U.S. gross domestic product (Chapter 5). If premiums for health insurance grow at the projected national rate of increase, the cost of family coverage will double from the 2008 average of $12,298 to $24,000 or even higher by 2020. Moreover, there is substantial evidence that the delivery system is inefficient and wasteful. Per capita expenditures for health care vary as much as 250% among communities of similar size, without any evidence that higher spending leads to better outcomes. In fact, observational data from Medicare suggest that there is actually an inverse relationship between the amount of overall health care spending at the state level and better quality.

Findings such as these have fueled demands from government, employers, and consumer groups for greater accountability and improved quality. In response, the information collected to measure health and health care has increased dramatically. Physicians and other health care providers are frequently confronted with these data in nearly every sphere of activity, including clinical care, education, and research. To interpret and apply this information correctly, health care providers should understand the basic principles of measuring the process and outcomes of health care.

MEASUREMENT OF HEALTH CARE

The basic paradigm that guides assessment of quality includes three fundamental domains: structure, process, and outcome. *Structure* refers to the stable elements that make up the health care system, such as the physical plant, administrative organizations, and qualifications of the staff. Because structural characteristics, such as whether floors are clean or doctors are board certified, are often the easiest aspects of health care to observe and measure, they were the main focus of early efforts to improve quality. Over time, however, it became clear that a clean environment and qualified providers are essential but insufficient to guarantee high quality unless the process of care is effective.

Process refers to how care is delivered, including medical interventions and interpersonal interactions. Thus it is important to know, for instance, whether the right physician has performed the right procedure on the right patient in the right way at the right time. Documenting these findings for the multitude of patients, however, can be expensive, difficult, and subjective because there may be a variety of acceptable approaches to a given clinical problem. Moreover, patients tend to be more concerned about achieving the best possible outcomes of care, such as curing disease, reducing symptoms, or improving function, than about how these outcomes are achieved.

Outcomes represent the presumptive results of care that is delivered. The concept of health outcomes encompasses a broad array of clinical indicators that include death, adverse clinical events, persistence or recurrence of disease, disability, discomfort, and pain. Outcomes from the patient's perspective include self-reported health, ability to function, burden imposed by disease, and satisfaction with care. In addition, there may be societal perspectives, such as cost-effectiveness and the cost-benefit ratio (Chapter 9). Judging care on the basis of outcomes is challenging because it may be difficult to measure outcomes reliably and because studies often fail to identify a relationship between high scores on process measures and better outcomes, such as lower in-hospital mortality. Indeed, recent studies of the quality of health care demonstrate that it is important to select measures that are adequately specified and provide a "tight" linkage between process and outcome.

STANDARDS OF MEASUREMENT

Irrespective of what aspect of health care is being evaluated, the measures used should satisfy standards that help ensure the trustworthiness of the data generated. These standards include adequate specification, reliability, validity, responsiveness, and interpretability. A measure that is *adequately specified* has a well-defined numerator that explicitly describes patients who meet the relevant criteria (e.g., patients whose blood pressure is <140/90 mm Hg or who are followed up within 2 weeks), a well-defined denominator (e.g., patients with hypertension or those discharged with heart failure), and a clear description of patients who are excluded from the calculation (e.g., patients who are younger than 18 years, who have not had an appointment within 18 months, or for whom only comfort care is being provided).

A *reliable* measure yields consistent results when repeated under similar circumstances. Although random error can never be eliminated, one would expect, for example, that two reviewers examining the same medical records would classify the outcomes in the same fashion in all but a small minority of cases. The level of reliability can be compared with common diagnostic procedures in medicine, many of which demonstrate only moderate reliability. For example, common methods of echocardiographic determination of ejection fraction vary up to 24% (Chapter 55), the intraclass coefficient for exercise treadmill tests performed a day apart is only 0.70, and the interobserver correlation for ascertaining the presence of coronary stenosis by highly trained experts is approximately 0.75 (Chapter 57).

Validity refers to the accurate measurement of an intended effect or outcome. In the case of physiologic measures, such as diagnosis of coronary artery disease with electron beam computed tomography (Chapter 56), validity would be indicated by the likelihood of coronary stenoses demonstrated angiographically. In actuality, demonstrable coronary stenoses are present in only 55 to 84% of patients who have a positive result on electron beam computed tomography, which makes it a relatively invalid outcome measure. Validity for measures of subjective outcomes, such as pain, is typically documented through correlation with other related measures, such as the use of analgesic medications or limitation of activities.

Responsiveness reflects the sensitivity of a measure to clinically meaningful changes in status. Whereas a patient with worsening osteoarthritis might record no change on an instrument assessing activities such as bathing or dressing, this patient might exhibit declining scores on a measure that addresses more vigorous activities.

These principles of measurement apply to both quality improvement and research studies, although the standards used in research are generally more rigorous. Measures are typically developed initially for use in research studies and, when shown to possess acceptable performance, are applied to routine quality improvement activities.

Additional criteria should be applied to measures that are being considered for routine use in a clinical setting (Table 10-1), including whether a measure

TABLE 10-1 CRITERIA FOR EVALUATING SUITABILITY OF A CLINICAL PERFORMANCE MEASURE

1. Are the performance characteristics of the measure well established—i.e., valid and reliable?
   - The measure appears to measure what is intended (face validity).
   - The measure captures most meaningful aspects of care (content validity).
   - The measure is reproducible over time and in multiple organizational settings (reliability).
2. Is the measure adequately specified?
   - Numerator: definition of patients meeting measure (e.g., patients with blood pressure <140/90 mm Hg or followed up within 2 wk).
   - Denominator: definition of patients qualifying for measure (e.g., patients with hypertension).
   - Included populations.
   - Excluded populations.
3. Is the measure likely to be useful in improving patient outcomes?
   - Scientific basis for the measure is well established.
   - The results of the measure are interpretable by individual(s) who are responsible for relevant activity.
   - The measure is actionable—i.e., addresses an activity or function that is under the control of individual(s) who are responsible and that is amenable to change.
   - Implementation of the measure is anticipated to promote the adoption of interventions that have the potential to improve patient outcomes substantially.
   - The clinical burden of the condition(s) related to the measure in the affected population is sufficient to warrant measurement and corresponding intervention.
   - Current levels of performance related to the measure within the health system indicate substantial opportunities of performance.
4. Can the measure feasibly be implemented?
   - The data required for the measure are likely to be obtained with reasonable effort, at reasonable cost, and within a reasonable time frame.
   - Data for the measure can be collected automatically when possible.
   - The measure has undergone adequate field testing.
5. The measure is relevant to the strategic goals of the health care system.

is *interpretable*, *evidence based*, *actionable*, *feasible,* and *relevant*. An interpretable measure can be understood and applied in clinical settings. For example, although most physicians understand the clinical implications of a change in arterial pH from 7.42 to 7.30, they might not have the same appreciation of a 20-point change on a 100-point scale that measures physical function or satisfaction. Moreover, a measure should be closely related to an intervention that has the potential to improve outcomes that are linked to the burden of the condition in the population.

TYPES OF MEASURES

Driven largely by efforts to compare the performance of providers and different health care systems, considerable effort has been expended to standardize measures at a national level. Examples include the Healthcare Effectiveness Data and Information Set (HEDIS), which is a set of standardized performance measures designed to assist purchasers and consumers in comparing the care and service provided by more than 90% of health plans in the United States. Another is ORYX, a set of national hospital quality measures collected by the Joint Commission on Accreditation of Healthcare Organizations (E-Table 10-1). Most of these are process measures, although some structural measures and intermediate outcome measures (see later) are included. The National Quality Forum (NQF), which is a quasi-public organization with more than 375 members from various sectors of the health care system, evaluates and issues endorsements for performance measures proposed by many different organizations.

Linkage between Process and Outcome Measures

Process measures are of greatest value when there is a close association, or tight linkage, between a process or action and an outcome. Numerous clinical trials, for example, have shown a substantial reduction in mortality when patients with hypercholesterolemia and ischemic heart disease are given a hydroxymethylglutaryl-coenzyme A reductase inhibitor (statin) to lower low-density lipoprotein cholesterol (LDL-C) levels (Chapter 213). Accordingly, the use of statins in appropriate patients is commonly used as an indicator of quality in many health care organizations. There are, however, limitations to using LDL-C measured at a single point in time; for instance, there may be a legitimate reason for LDL-C to be over the target range in as many as half of patients who would otherwise appear to have received poor-quality care. Such reasons include having only recently started taking statins, and the dosage is still being titrated; having refused therapy; having a high LDL-C level despite maximal therapy; or having experienced an adverse effect of statins.

Intermediate and Combined Outcomes

Because many outcomes of interest, such as death or the occurrence of serious adverse events, may be relatively infrequent, *intermediate* or *surrogate outcomes* are sometimes measured instead of the true outcome of interest. Intermediate outcomes are often physiologic variables such as blood pressure, cholesterol level, or hemoglobin A_{1c} concentration. For example, the primary rationale for treating diabetes is to prevent complications such as blindness, amputation, or renal failure, and the efficacy of treatment should ultimately be determined by a reduction in risk for these complications. Though important in the pathophysiology of diabetes, a change in the measured hemoglobin A_{1c} level is meaningful as an outcome measure (particularly to the patient) only insofar as it reflects a reduction in risk afforded by treatment. As opposed to standard physiologic measures, other intermediate outcomes reflect subclinical disease; for example, microalbuminuria indicates subclinical renal disease in diabetes (Chapter 236). Intermediate outcomes are attractive because they are often familiar to clinicians and can readily be measured repeatedly in most or all patients, whereas the outcome of interest (e.g., amputation) is a relatively infrequent event in patients treated for diabetes. Using intermediate outcomes may be deceptive, however, particularly when the linkage to the true outcome of interest is loose. The presence of microalbuminuria in a patient with type 2 diabetes (Chapter 237), for instance, is associated with a 2½-fold increase in the relative odds of dying over a 6-year period when compared with diabetic patients who have no protein in their urine. This sizable increase in relative risk, however, translates into a relatively small increase in absolute risk for any individual in any given year. Thus, changes in quality as measured by rates of microalbuminuria would probably not be reflected in outcome measures such as the incidence of cardiovascular events or renal failure, except in extremely large populations. Moreover, it is possible for a treatment to have a salutary effect on a surrogate outcome but a deleterious effect overall. Such was the case for short-acting dihydropyridines such as nifedipine, which effectively lowered blood pressure in hypertensive patients but doubled the incidence of myocardial infarction.

Another strategy adopted when outcome events are infrequent is the use of combined end points. An example is the incidence of cardiovascular events, including stroke, myocardial infarction, unstable angina, and sudden cardiac death. This approach can improve the statistical power of a study, but it tends to exaggerate the perceived efficacy of a particular intervention and may obscure specific effects, such as when an intervention reduces the frequency of stroke more than it does myocardial infarction.

Patient-Oriented Measures

Although physiologic and standard clinical measures are important, the assessment of outcomes from the patient's perspective has increasingly been recognized as being of equal or even greater importance, especially when evaluating treatments intended to lessen symptoms or improve function rather than improve survival. Approaches that depend on a physician's perception of a patient's condition, such as the Canadian Cardiovascular Society Classification for cardiac symptoms (Chapter 50), are limited because physicians often tend to underestimate a patient's symptoms or disability, and such assessments are difficult to standardize. Self-reporting of health and function by patients themselves via standardized questionnaires overcomes these problems. The terminology used to describe the hundreds of questionnaires now available is evolving and, at times, confusing, but the resulting scales generally address various aspects of health-related quality of life, which is a complex, multidimensional concept. Facets or subscales of quality of life may include the severity of symptoms, pain, physical functioning, social functioning, general perceptions of health, overall burden of disease, emotional well-being, and coping, among others.

General measures of health status or health-related quality of life, such as the Short-Form 36 (SF-36), do not focus on a specific disease or condition but seek to assess overall health and functioning. General measures may, however, be insensitive to a specific yet clinically meaningful change in symptoms related to a particular condition. For this reason, more than 1000 *condition-specific measures* are now available. Whereas a patient's score on a questionnaire dealing with overall health might not change in response to successful treatment of a specific condition, such as gastroesophageal reflux,

the score on a questionnaire specifically addressing symptoms of heartburn would register a substantial change.

In the past, measures of self-reported health were criticized as being "soft" and overly subjective. In fact, many general and condition-specific measures demonstrate reliability and validity that equal or exceed those of many physiologic or clinical measures commonly used in research or clinical settings. For example, among patients undergoing coronary artery bypass grafting (Chapter 74), a 10-point reduction in self-reported physical functioning (on a 100-point scale) increases the risk for death by the same magnitude that the presence of diabetes or chronic obstructive pulmonary disease does.

A shortcoming of nearly all outcome measures other than death is that it is difficult or impossible to use such measures to compare alternative treatments unless they are applied in precisely the same fashion. In the case of hypertension (Chapter 67), for example, different drugs might exhibit differential effects on the risk for stroke or heart failure and also on the risk for adverse events such as fatigue, hepatotoxicity, or renal insufficiency. *Utility measures,* which are derived from economic and decision theory, seek to provide a standard method of comparing such disparate outcomes. *Utility* is the value or preference that an individual places on a given state of health or condition. Utility is scored from 0 (generally equivalent to death) to 1.0 (ideal health). Multiplication of individual utilities for different health states by their probabilities of occurrence permits computation of the overall utility of a treatment or intervention and enables comparison with therapeutic alternatives through the technique of decision analysis. When combined with probabilities of survival, utility can be used to calculate quality-adjusted life years, yet another way of comparing outcomes of different treatment strategies (Chapter 9). Outside the research setting, however, utilities have not been widely used because they are difficult to elicit from patients.

Patients' experiences with health care are commonly measured by standardized questionnaires, such as the Consumer Assessment of Healthcare Providers and Systems (CAHPS) family of surveys, which were developed through a public-private partnership and include instruments used in both ambulatory and institutional settings. Like health-related quality of life, patient experience is a broad concept that can incorporate a number of different dimensions, including satisfaction with overall health care, systems of care, hospital care, outpatient care, specific types of treatments, individual health care providers, amenities, and other aspects. Because patients' perceptions of their care may not correlate highly with other aspects of the processes and outcomes of care, results must be interpreted in the context of these other measures.

Measures of Cost and Resource Use

Given the dramatically rising expense of health care, costs are frequently measured. Because of the complexity of the health care market, including contractual arrangements and complicated formulas for reimbursement, charges (prices) rarely represent the true underlying cost of services. Therefore, careful accounting methods are necessary to accurately ascertain cost. Because these methods can be laborious and expensive, *utilization* of health care services, such as average length of stay or number of days in intensive care units, is often measured as a proxy for cost. When actual costs are measured, the costs evaluated are generally those characterized as *direct,* or the actual fixed and variable expenses for labor, materials, and equipment necessary to provide a given clinical service. Because these costs are typically the responsibility of insurers and health systems, analyses that use direct costs assume their viewpoint. When more global perspectives are incorporated, including those of patients, it is also necessary to measure *indirect costs,* such as the loss of time and the inconvenience incurred by patients or the societal burdens of disability or loss of productivity. Naturally, indirect costs are even more difficult and expensive to measure than direct costs.

From a policy or decision-making perspective, information about cost is most useful when it permits comparisons of alternatives, such as different drugs to treat hypertension. *Cost-benefit* analysis attempts to summarize all costs of treatment and all potential benefits solely in monetary terms. This approach is controversial and is not frequently applied because it necessitates assigning dollar costs to outcomes such as death or disability. *Cost-effectiveness* analysis is performed more frequently because the results are expressed in more comprehensible clinical terms, such as cost per life saved or per quality-adjusted life year (using the utilities described earlier). When a new treatment is evaluated, it is desirable to calculate its *marginal cost-effectiveness,* which describes its costs and benefits in relation to an existing standard treatment.

SOURCES OF DATA FOR THE MEASUREMENT OF HEALTH AND HEALTH CARE

Under ideal circumstances, data for measuring health care are collected prospectively with techniques and instruments specifically designed for the patient population and the problem being assessed. In reality, the time and expense required to develop or identify measures and collect primary data are often too prohibitive to address many important questions. In these situations, it can be advantageous to use information collected for administrative or billing purposes that reflects the process of health care. Such secondary sources of data have increasingly been applied to a broad range of topics, including the use and outcomes of all types of health services.

Governmental Sources of Data

Historically, federal and state governments have collected data related to public health, such as the occurrence of communicable diseases or causes of death. With the expansion of publicly funded health programs such as Medicare and Medicaid, the rise in chronic illnesses as a major cause of morbidity and mortality, and the advent of programs to promote quality and consumer awareness through public reporting of performance data, governmental agencies now maintain a broad range of databases, many of which can be accessed via the Internet (E-Table 10-2). These databases make available vast amounts of information about the incidence and prevalence of various medical conditions, characteristics of patients and health care providers, types of health care services used, burdens and cost of illness, and other important health outcomes, such as adjusted mortality.

Clinical and Quality Data

Until the latter part of the 20th century, most statistics on health care delivery and on the health of groups of patients (with the exception of individual medical records) were maintained by governmental agencies. Today, there are hundreds of public and private entities that collect, process, analyze, or disseminate this information. The consolidation of health care delivery systems within markets and the wide use of electronic health records have led to the creation of very large and rich clinical databases that can be an excellent source for monitoring and improving the quality of care. These data sources can furnish clinical details about the severity and clinical course of illnesses not obtainable from administrative databases.

Another emerging source of data is quality measurement systems developed by peer review organizations, medical care organizations, health plans, professional organizations, consumer organizations, and bodies that perform accreditation. To a greater or lesser extent, all these groups have developed systems to measure and evaluate the performance of health care providers and systems. These data may be collected through the extraction of data from secondary sources, manual abstraction of physical or electronic medical records, or primary data collection by clinical or administrative personnel. Despite the relatively low expense, ready availability, and large size of secondary data sources, there are serious potential limitations to their use (Table 10-2).

DESIGN OF MEASUREMENT STUDIES

Data used to measure the structure, process, and outcomes of health care are obtained in a variety of ways. Investigators engaged in hypothesis-driven research often apply rigorous methods of measurement and research designs, whereas those evaluating the quality of care provided within and among health care organizations tend to rely on observational studies or secondary sources of data (i.e., data initially collected for a different purpose, such as clinical care or claims processing). However, progressive overlap in the methods used and the proliferation of computerized data sources have begun to blur the boundaries between certain types of research and quality improvement studies.

Experimental Studies

Evaluation of the effects of treatments on clinical outcomes should generally be performed in randomized, controlled trials in which the intervention is randomly assigned to ensure that patients who do (subjects) and do not (controls) receive it are as similar as possible. In double-blind studies, not only the patient but also the patient's physician and certain members of the investigative team are kept uninformed about the treatment assignment. Maintenance of blinding is more difficult in studies of interventions other than drugs, but even in studies of surgery or acupuncture, for example, control patients can undergo sham procedures. In studies evaluating more

TABLE 10-2 POTENTIAL LIMITATIONS OF SECONDARY DATA

FEATURE	POTENTIAL LIMITATIONS
Accuracy and precision of data	Basic information on patient characteristics, diagnoses, and procedures may be miscoded Data generally available only for people who use services or access the health care system during the period of interest Patients may be miscounted if they have multiple sites of residence or have undergone procedures in more than one system of care
Sample size	Large sample sizes may produce statistical significance without clinical or policy significance
Characterization of patients	Patients are incompletely characterized; key clinical data on processes and outcomes may be missing
Characterization of providers	Characteristics of providers may be missing, miscoded, or inconsistently recorded
Characterization of interventions	Services or procedures may be coded imprecisely or inaccurately
Ascertainment of outcomes	Outcomes of greatest relevance may not be captured (e.g., symptom relief, quality of life, out-of-hospital events, level of satisfaction)
Completeness of follow-up	Only data about discrete episodes of care may be coded; longitudinal follow-up requires data linkage, which may not be possible

Adapted from Huston P, Naylor CD. Health services research: reporting on studies using secondary data sources. *Can Med Assoc J.* 1996;155:1697-1702.

complex interventions, such as use of a team to manage diabetes or heart failure, blinding may be impractical. To help maintain equivalence in such cases, patients serving as controls may receive a less intensive intervention to help ensure that any observed difference in health outcome between the experimental and control groups is the result of genuine treatment effects rather than nonspecific effects of increased attention.

In trials of interventions that are applied directly to patients, such as medications or procedures, allocation of the experimental treatment is generally random by patient, and results are analyzed at the level of the patient. Conversely, in trials of interventions designed to improve how care is delivered, the unit of randomization and analysis may be the patient, the health care provider, or even the entire system of care, depending on the level at which the intervention is administered. In studying the clinical effects of an educational quality improvement program targeted toward physicians, for example, participating physicians should be randomized along with their patient panels, because the effects on patients within a panel would not be independent. Similarly, in a study of a new way to organize personnel within a practice to treat depression, entire practices might be the correct unit of randomization and analysis.

Although the randomized, controlled trial is the most rigorous method of assessing treatment effects, this approach has several shortcomings. To achieve equivalence between treatment and control groups with respect to key demographic and clinical characteristics, eligibility is often restricted to a narrow range of individuals who fulfill strict criteria. Although this approach enhances the internal validity of a trial's results, applicability of the results to groups of patients who would have been deemed ineligible for the trial (often elderly or chronically ill patients) remains uncertain. Moreover, to help ensure that patients fully comply with the treatment being tested, study personnel frequently provide substantially more support and assistance to participants than similar patients would receive in ordinary clinical settings. These differences often raise concerns about the *external validity* or generalizability of results. For this reason, tightly controlled randomized trials are often considered to establish the *efficacy* of an intervention—specifically, the potential benefit of an intervention under ideal conditions. To establish whether an intervention is successful in patients more typically seen in routine practice, investigators may conduct an *effectiveness trial,* also known as a *management* or *pragmatic trial.*

Other potential drawbacks of randomized trials are the long time required for planning and execution, the high expense, and the low statistical power to assess infrequent outcomes, especially for studies in which health care providers or systems of care are randomized. To compensate in part for these drawbacks, *cluster randomized trials* are designed to permit randomization at the level of the provider or system, but they use sophisticated statistical techniques (e.g., multilevel or hierarchical regression) to perform analyses at the level of the patient so that statistical power is preserved. This approach is particularly well suited to effectiveness trials, which often involve testing of clinical strategies or programs. Other novel approaches are sequential methods, such as the *group sequential response* and *adaptive clinical trial* designs, which provide an opportunity to terminate a study, adjust the expected sample size, or modify the intervention as the trial progresses on the basis of interim analysis at predetermined points in time. These approaches, which are especially attractive when preliminary data are limited, can enhance efficiency by terminating positive or negative trials earlier than might be the case when using only initial sample size estimates.

Nonexperimental Designs

Although randomized trials remain the best approach to assess the efficacy of therapeutic interventions, other study designs, such as *observational* or *case-control* studies, are often used under certain circumstances. *Cohort* studies are a type of observational study in which one or more groups of patients are selected because they have or have not been exposed to a particular condition or intervention. Exposures can be broadly defined and can include the presence of a particular disease or condition (e.g., pneumonia or heart failure), receipt of a type of medication, provision of a certain medical service (e.g., surgical procedure) or set of services (e.g., care by a specialist physician or enrollment in a particular type of health plan), or exposure to a set of conditions (e.g., having health insurance). Cohort studies have numerous attractive features, including the ability to provide a direct estimate of the absolute risk for an outcome in exposed patients. The foremost liability of these approaches is that any observed difference in outcomes may be due to inherent differences between patients who do and do not receive the intervention because it is not randomly allocated. This dilemma can often be addressed by using statistical methods for *case mix adjustment* (described in the next section). In some circumstances, however, even extensive adjustment is inadequate, such as when there is *bias by indication.* This problem occurs in the study of a relationship between an exposure (e.g., a short-acting calcium-channel blocker) and an outcome (e.g., myocardial infarction) when one indication for the medication is treatment that is directly related to the outcome (i.e., angina pectoris). One solution to this problem is to eliminate patients for whom this bias is likely to be present. In the illustrative case, a heightened risk for myocardial infarction in patients taking short-acting calcium-channel blockers was initially demonstrated in a study restricted to persons with hypertension but no known cardiovascular disease.

In a *prospective cohort study,* participants are identified at the time of exposure and followed forward in time according to a predefined protocol and with standard measures. Prospective cohort studies often permit the enrollment of a broader cross section of patients than is possible in randomized trials and can be conducted under circumstances in which randomization is not feasible for ethical or logistic reasons. Like randomized trials, prospective cohort studies provide a means to ascertain that the exposure under study truly precedes the outcome of interest. Limitations of prospective cohort studies include the need to enroll large numbers of patients (especially when evaluating rare outcomes), the frequent loss of participants during follow-up, and the high expense, often related to the duration of follow-up.

In a *retrospective cohort study,* exposure is typically defined by using secondary data (e.g., an admitting diagnosis of acute myocardial infarction or a procedure code for spinal fusion on a hospital discharge abstract) at some point in the past, and patients are followed forward in time by using previously collected data for outcomes (e.g., death, reoperation, readmission). Formerly, retrospective cohort studies were limited in time and scope because they relied on the often tedious manual abstraction of medical charts. With the proliferation of secondary electronic data sources, this approach has become extremely popular and has several advantages—chiefly, the opportunity to study vast numbers of patients inexpensively, including those with relatively rare conditions. Standardized coding for many variables, such as diagnoses and procedures, helps reduce the variability introduced by human chart abstractors. Moreover, electronic records are far less apt to be unavailable or incomplete than paper records are. However, retrospective cohort studies are subject to a number of potentially serious flaws. Hypotheses are usually generated and studies designed well after the collection of data, which was generally done for a wholly different purpose. Thus, the reliability and validity of the data are often unknown and beyond the control of the

investigator. This problem can lead to misclassification of both exposures and outcomes. For example, a diagnosis of pneumonia coded for billing purposes may not satisfy the rigorous criteria used in research. Although a patient's complete electronic record is rarely lost, missing data within records are common. Unlike with prospective studies, it may be difficult to be certain that an exposure preceded an outcome. For example, a patient might have had subclinical disease at the time of a given exposure, thereby leading to an erroneous impression of a temporal sequence when the disease was recognized clinically. Apart from methodologic limitations, the sheer volume of available data encourages investigators to conduct numerous analyses, often without prestated hypotheses. Multiple comparisons performed with very large sample sizes readily lead to erroneous conclusions that random associations are clinically meaningful because they are of marginal statistical significance.

Case-control studies differ from cohort studies in that the case and control groups are defined on the basis of whether subjects have experienced an outcome rather than on the basis of exposure. Data from existing records or gathered by interview (or both) are then used to ascertain the proportion of case and control patients who experienced the exposure of interest. As in cohort studies, exposures can be defined broadly, including a medication, a type of clinical event, or receipt of a service. Case-control studies are attractive in many settings because they require fewer patients than prospective studies do to achieve a similar level of statistical power. This attribute makes them especially useful for investigating uncommon outcomes. For example, pharmacoepidemiologists often use case-control studies to identify serious adverse effects of medications when the events are too rare to study with clinical trials or cohort studies. Case-control studies are nonetheless subject to a number of potential biases. As with cohort studies, the use of data from secondary sources can lead to misclassification of exposure or outcome. When exposure is determined by interview, differential recall by cases and controls can introduce bias. It may be even more difficult to be certain that an exposure truly occurred before the outcome than in retrospective cohort studies. Furthermore, the results of case-control studies do not yield estimates of absolute risk, as do randomized trials and cohort studies; they are expressed as the odds of an outcome in cases relative to controls. *Relative odds* only approximate the ratio of risk in cases to risk in controls.

Cross-sectional studies are performed when data on one or more groups of patients are collected at a single point in time. Although this approach is inexpensive and can provide estimates of the prevalence of a condition or outcome, it is highly subject to nearly all the biases mentioned and is the weakest method in terms of making inferences about whether a particular exposure directly causes a given outcome.

Case Mix Adjustment

Only in prospective, randomized trials is it possible to control which patients do and do not receive a specific treatment, and even then, it may not be possible to ensure the equivalence of all the characteristics that affect outcomes between subjects in the control and experimental groups. In all nonexperimental research designs, allocation of the experimental intervention is not random but is a function of a patient's personal and clinical characteristics and those of the system of care. Without consideration of such differences, it is impossible to differentiate the genuine effects of an intervention from bias related to allocation of the intervention to certain types of patients. Modern statistical techniques that can adjust for such differences are effective when many of the patient characteristics that exert an important influence on outcomes have been elucidated and relevant data are available. For example, the major factors that predict mortality after acute myocardial infarction include prolonged chest pain, tachycardia, hypotension, ST segment elevation on the admission electrocardiogram, poor left ventricular function, and initial laboratory measures that indicate a large infarct, such as a high troponin level. Thus, when comparing the outcomes of patients who are treated in different systems of care, it is essential to use multivariate statistical methods to adjust for these factors. Otherwise, differences observed between systems that are actually due to differing patient populations might erroneously be attributed to differences in quality of care. A related method is *propensity scoring*, which applies the results of modeling equations that predict how likely a person was to have received one intervention or the other based on personal and clinical characteristics. Even with sophisticated adjustments, however, studies of treatments that rely heavily on the judgment of physicians or the preference of patients are likely to have biases that cannot be addressed by statistical modeling and require randomized trials.

TABLE 10-3 EXPANDING AREAS OF STUDY FOR HEALTH CARE QUALITY AND OUTCOMES

GENERAL AREA OF STUDY	EXAMPLE OF INTERVENTION OR OUTCOME EVALUATED
Effectiveness of clinical programs	Disease management programs, specialized clinics, consultative services
Organization of care	Health maintenance organizations vs. private practice
Effects of different mechanisms of financing	Capitation vs. fee-for-service; different levels of pharmacy copayments
Outcomes of different types of providers	Generalists vs. specialists
Disparities among ethnic groups	Receipt of preventive services or sophisticated procedures
Patient safety	Occurrence of adverse drug effects or medical errors
Geographic variations in patterns of care	Use of expensive procedures

TRENDS IN OUTCOME MEASUREMENT

In recent years, the topics of studies evaluating the outcomes of health care interventions have expanded greatly. In addition to evaluating specific treatments, such as drugs or procedures, evaluations directly compare various types of clinical programs, systems of care, types of providers, mechanisms of financing, patient safety, disparities among ethnic groups, and geographic variations in patterns of care (Table 10-3). Recently, public attention has been focused on *comparative effectiveness,* which reflects the need to evaluate new and typically more expensive therapies in relation to older, well-established treatments, as opposed to the common practice of merely comparing them with placebo or clearly less effective regimens. Information from such trials is essential to identify the most cost-effective therapies.

It is safe to predict that studies on the processes and outcomes of health care will become even more ubiquitous with the expanding availability of electronic data, increasingly sophisticated statistical techniques, and growing public demand for accountability.

QUALITY OF CARE AND PATIENT SAFETY

ROBERT M. WACHTER

During the past two decades, scores of studies have demonstrated that the quality and safety of modern health care leave much to be desired, despite the fact that most physicians are well trained and work very hard. Yet the evidence is undeniable, with clear documentation of stunning variations in patterns of care that are neither supported by evidence nor justified by outcomes, major gaps between evidence-based best practices and current practice, and staggering numbers of serious medical errors. The recognition of these quality and safety problems has catalyzed a major transformation in thinking and practice, with new technologies, regulations, training models, incentive systems, and more.

TABLE 11-1 THE INSTITUTE OF MEDICINE'S SIX QUALITY AIMS

Patient safety
Patient centeredness
Effectiveness
Efficiency
Timeliness
Equity

From Committee on Quality of Health Care in America, Institute of Medicine. *Crossing the Quality Chasm: A New Health System for the 21st Century*. Washington, DC: National Academy Press; 2001.

To appreciate the problem and how to address it requires an understanding of quality measurement and improvement, the safety of patients, and value, which is the confluence of safety, quality, and cost.

QUALITY

Definition

Quality of care has been defined by the Institute of Medicine as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." It includes six aims for a quality health care system, emphasizing that quality involves more than the delivery of evidence-based care (Table 11-1). Nevertheless, evidence-based medicine (Chapter 9) provides much of the scientific underpinning for quality measurement and improvement. Previously, the lack of clinical evidence and the apprenticeship model of medical training promoted an idiosyncratic practice style by which a senior clinician or a marquee medical center determined the standard of care—a tradition now sometimes termed *eminence-based medicine*. Without discounting the value of experience and mature clinical judgment, the modern paradigm for determining optimal practice has changed, driven by the explosion in clinical research during the past 30 years; for example, the number of randomized clinical trials grew from 350 per year in 1970 to 18,000 per year in 2008. This research has helped define "best practices" in many areas of medicine, from preventive strategies for a healthy 62-year-old outpatient (Chapters 13 and 14) to the treatment of a patient with acute myocardial infarction and cardiogenic shock (Chapters 73 and 107).

Donabedian's triad, which divides quality measures into *structure* (how care is organized), *process* (what is done), and *outcomes* (what happens to the patient), represents the most popular construct for quality measurement. Each element of the triad has important advantages and disadvantages as a quality measure (Table 11-2). Most of the widely used quality measures are process measures for which clinical research has established a link between such processes and improved outcomes. An example is the rate at which aspirin or a β-blocker is given to survivors of a myocardial infarction before hospital discharge (Chapter 73). However, when processes are less relevant and the science of case-mix adjustment is suitably advanced (e.g., cardiac bypass surgery; Chapter 74), outcome measurement is often used. In other areas involving complex processes, structural measures are used as proxies for quality; examples here include the presence of intensivists to staff critical care units, a dedicated stroke service, and computerized physician order entry (CPOE) systems.

TABLE 11-2 COMPARISON OF THREE MEASURES OF CLINICAL QUALITY: THE DONABEDIAN TRIAD

MEASURE	SIMPLE DEFINITION	ADVANTAGES	DISADVANTAGES
Structure	How was care organized?	May be highly relevant in a complex health system	May fail to capture the quality of care by individual physicians Difficult to determine the "gold standard"
Process	What was done?	More easily measured and acted on than outcomes May not require case-mix adjustment No time lag—can be measured when care is provided May directly reflect quality (if carefully chosen)	A proxy for outcomes Not all may agree on "gold standard" processes May promote "cookbook" medicine, especially if physicians and health systems try to "game" their performance
Outcomes	What happened to the patient?	What we really care about	May take years to occur May not reflect quality of care Requires case-mix and other adjustment to prevent "apples-to-oranges" comparisons

Modified from Donabedian A. The quality of care. How can it be assessed? *JAMA*. 1988;270:1743-1748; and Shojania KG, Showstack J, Wachter R. Assessing hospital quality: A review for clinicians. *Eff Clin Pract*. 2001;4:82-90.

The Epidemiology of Quality-Related Problems

It is now well established that there are large and clinically indefensible variations in care from one city to another. Furthermore, U.S. practice adheres to the best evidence only slightly more than 50% of the time, even when adherence is known to correlate with ultimate clinical outcomes.

Levers for Change

For physicians, policymakers, administrators, and patients, evidence of major problems with quality has led to the recognition of structural problems that prevent the delivery of the highest quality of care. These problems include the lack of information regarding the performance of a provider or institution, the absence of incentives for quality improvement, the challenge for practicing physicians to stay abreast of modern evidence-based medicine, and the absence of an information technology support system for quality.

The first step in quality improvement is the creation of practice standards against which to measure quality. Scores of such measures have been promulgated by a variety of organizations, including payers (such as the Centers for Medicare and Medicaid Services), accreditors (such as the Joint Commission), and medical societies. These measures have identified many opportunities for improvement among individual physicians, practices, and hospitals.

Given the volume of new literature published each year, it is impossible for an individual physician to keep up with all the evidence-based advances in his or her field. *Practice guidelines,* such as those for the treatment of community-acquired pneumonia (Chapter 97) or the prophylaxis of deep venous thrombosis (Chapter 81), aim to synthesize evidence-based best practices into a set of summary recommendations. Although concerns about "cookbook medicine" linger, there is a growing consensus that best practices should be "hardwired" if possible. The major challenges are to update guidelines as new knowledge accumulates and to recognize the complexity of guidelines when patients have multiple, potentially overlapping illnesses. *Clinical pathways* are similar to guidelines but attempt to codify a series of steps, usually temporally (on day 1, do the following; on day 2, do the following; and so forth), making them more useful for stereotypical processes such as the postoperative management of patients after hip replacement.

Although professionalism (Chapter 1) should be a sufficient incentive for physicians to provide high-quality care, reaching this goal typically depends on the existence of a system organized to translate research into practice and to deliver the right care every time. Such a system requires significant investments (in educating physicians, hiring case managers or clinical pharmacists, building information systems, and developing guidelines). The historical payment system, which compensates physicians and hospitals equally whether quality is terrific or terrible, provides no incentive to make the requisite investments.

The Changing Environment for Quality

The recent recognition of major gaps in quality and of the need for systemic change to improve quality has led to a variety of initiatives to catalyze quality improvement. Virtually all involve several steps: defining reasonable quality

measures (evidence-based measures; capturing appropriate structures, process, or outcomes), measuring the performance of providers or systems, and using these results to promote change. This final imperative creates the greatest degree of uncertainty and experimentation.

Although one might hope that simply giving a physician information about prior performance would generate meaningful improvement, this strategy yields only modest change at best. Increasingly, a more aggressive and transparent strategy, such as disseminating the results of quality measurement to key stakeholders, is being adopted. In some cases, simple transparency is the main strategy—the rationale being that providers will find the exposure of their gaps in quality to be sufficiently concerning or embarrassing to motivate improvement. Although there is little evidence that patients use such data to choose among physicians or hospitals, transparency itself has frequently resulted in impressive improvements in some publicly reported quality measures.

The newest strategy in the United States is to tie payments for service to quality performance (pay for performance, or P4P). A number of P4P programs are under way, and early results indicate that differential payment leads to modest gains beyond the improvements achieved by simple transparency. P4P also raises a host of concerns, including whether presently captured quality data are accurate, whether payments should go to the best performers or those with the greatest improvements, whether existing measures adequately measure quality in patients with complex diseases, and whether P4P will create undue focus on certain measurable practices, leading to relative inattention to other important processes that are not being compensated. A recent variation on the P4P theme is Medicare's "no pay for adverse events" program, in which hospital payments are withheld for certain "preventable" adverse events. As with P4P more generally, the jury is still out regarding the impact of such programs on quality and safety.

Quality Improvement Strategies

Whether the motivation is professionalism, embarrassment, or economics, the next question is how actually to improve the quality of care. There is no simple answer; successful institutions and physicians have used a variety of strategies. In general, most use a variation of a "plan, do, study, act" (PDSA) cycle, recognizing that quality improvement activities must be carefully planned and implemented, that their impact needs to be measured, and that the results of these activities are often imperfect and require retooling.

In addition to the PDSA cycle, several other types of activities are useful. For quality improvement practices that require predictable repetition, efforts to "hardwire" the practice or to use alternative providers who focus on the activity are often beneficial. For example, the best strategy to increase the rate of pneumococcal vaccination (Chapter 17) among hospitalized patients with pneumonia is to embed it in a standard order set, either paper based or computerized. Another example is that having a nurse remove patients' shoes before the physician's entry can increase rates of diabetic foot examinations in an outpatient practice (Chapter 236).

In some areas, though, quality improvement involves much more complex and interdependent activities. In these circumstances, bringing teams together to examine their practices and to participate in a PDSA cycle is the most likely path to success. For example, a group of cardiac surgeons in the northeastern United States participated in an experiment in which they observed one another's practices, agreed on best practices, and measured one another's outcomes; the result was a 24% reduction in mortality with cardiac surgery.

PATIENT SAFETY

Epidemiology

The concept of "first, do no harm" began more than 2 millennia ago, and many hospitals host periodic forums (e.g., morbidity and mortality conferences) to discuss errors. Until recently, however, there has been little teaching about the nature of medical mistakes, investment in safety research, regulation of safety standards, or emphasis on safety improvements, despite the fact that an estimated 44,000 to 98,000 Americans die each year of medical mistakes—the equivalent of a jumbo jet crashing each day. Such deaths may be related to medication errors, gaps in the discharge process, communication problems in intensive care units, or retained sponges in surgical patients—in short, virtually every aspect of modern medical care. Moreover, detailed clinical and statistical evidence of suboptimal safety has been reinforced by several high-profile and disquieting errors, sometimes apparently related to inadequate supervision and prolonged duty hours of trainees. These errors include the wrong patient getting a major procedure, the wrong limb being operated on, chemotherapy overdoses, mistaken mastectomies, and more.

Because patients may be harmed despite receiving perfect care (i.e., from an accepted complication of surgery or a side effect of medication), it is important to separate *adverse events* from *errors*. The patient safety literature commonly defines an error as "an act or omission that leads to an unanticipated, undesirable outcome or to substantial potential for such an outcome." Adverse events, in contrast, are injuries due to medical management rather than the patient's underlying illness. This distinction is crucial. For example, when a patient who was appropriately prescribed warfarin for chronic atrial fibrillation (Chapter 64) develops a gastrointestinal bleed despite a therapeutic international normalized ratio (INR), an adverse event, not a medical error, has occurred. Conversely, if the INR was supratherapeutic because the physician prescribed a new medication without checking for possible drug interactions, a medical error would have occurred.

The Modern Approach to Patient Safety

The historical approach to medical errors often has been to blame the provider who was most proximate: whoever performed the surgery, hung the intravenous medication, or mixed the chemotherapy. It is now recognized that this approach fails to appreciate that most errors are committed by hard-working, well-trained individuals, and such errors are unlikely to be prevented by admonishing people to be more careful or by shaming and suing them. Instead, the modern approach, known as *systems thinking*, holds that humans will inevitably err and that safety depends on creating systems that anticipate errors and either prevent or catch them before they cause harm. Such an approach has been the cornerstone of safety improvements in other high-risk industries for some time.

The "Swiss cheese" model of accidents, drawn from innumerable investigations of accidents in commercial aviation and the nuclear power industry, for example, emphasizes that single errors by one individual working in an otherwise safety-conscious system rarely cause harm. Instead, such errors must penetrate multiple incomplete layers of protection ("layers of Swiss cheese") to cause terrible harm. The lesson is to focus not on the futile goal of trying to perfect human behavior but rather on creating multiple overlapping layers of protection to decrease the probability that the holes in the Swiss cheese will ever align, allowing an error to slip through.

How to Improve Patient Safety

Drawing on these models, modern thinking emphasizes efforts to design and implement systems to prevent or catch errors. For example, errors in routine behaviors can best be prevented by building in redundancies and crosschecks in the form of checklists, read-backs, and other standardized safety procedures, such as counting sponges in the operating room, signing a surgical site before an operation, or asking patients their names before administering a medication. In recent years, the use of checklists for the placement of central lines and to prepare patients for surgery has resulted in remarkable reductions in morbidity and mortality. One way to decrease errors at the person-machine interface is by the use of "forcing functions," engineering solutions that decrease the probability of human error. The classic example outside of medicine is the modification of automobile braking systems to make it impossible to place a car in reverse when the driver's foot is off the brake. In health care, forcing functions include changing the gas nozzles and connectors so that anesthesiologists cannot mistakenly hook up the wrong gas, such as nitrogen instead of oxygen, and administer it to a patient. Given the ever-increasing complexity of modern medicine, building in such forcing functions in intravenous pumps, defibrillators, mechanical ventilators, and computerized order entry systems will be crucial to safety.

In addition to better systems, communication and teamwork must be improved. All commercial pilots must take "crew resource management" courses, in which they train for emergencies with other crew members, learn to flatten hierarchies that might stifle open communication, communicate clearly with standard language, and use checklists and other systemic approaches. Recent evidence supports that such interventions in medical care can lead to fewer errors and improved outcomes. The goal is a "culture of safety"—an environment in which teamwork, clear communication, and openness about errors, both with other health care professionals and with patients, is the norm. A tailored group of discharge services, emphasizing both process improvements and better collaboration among providers, can significantly reduce hospital readmissions,■ and a multidisciplinary fall prevention program can reduce falls in hospitalized patients.■

Another key principle in ensuring the safety of patients is to learn from one's mistakes. Safe systems have a culture in which errors are openly discussed, often in morbidity and mortality conferences. To be most useful, these discussions should be interdisciplinary (involving doctors and other health professionals), identify when the errors occurred, and emphasize systems thinking and solutions; they should not be punitive. In addition to open discussions during conferences, safe organizations build in mechanisms to hear about errors from frontline staff, often through "incident reporting systems"; they also perform detailed "root cause" analyses of major errors or "sentinel events" in an effort to define all the layers of Swiss cheese that need improvement. The importance of open communication extends to patients as well. Disclosure of errors is now required by the Joint Commission. Patients and families value such openness, and preliminary evidence indicates that disclosure of errors might decrease the chance of a malpractice suit.

Finally, there is increasing appreciation of the importance of a well-trained, well-staffed, and well-rested work force for the delivery of safe care. Lower nurse-to-patient ratios, long work hours for residents, and lack of board certification are all linked to poor outcomes for patients. Safer systems cannot be created if the providers are overextended or poorly trained or supervised.

In the absence of comparative evidence, and in light of the high cost of interventions such as improved staffing, computerized order entry, and teamwork training, even institutions committed to safety must often make difficult choices. Given the natural tendency to focus on practices that are measured, publicly reported, and compensated, institutions and physicians tend to focus first on areas that are subject to regulation or on initiatives with multiple potential benefits, such as computerization. Because improving culture is difficult to measure and to regulate, there is concern that it will not be as high a priority as it should be. Moreover, a safe culture depends on balancing the imperative to improve systems with the need to define and enforce accountability. The safety field is increasingly emphasizing more active enforcement of policies that address problems such as disruptive behavior by clinicians and failure to adhere to evidence-based safety practices.

VALUE: CONNECTING SAFETY AND QUALITY TO COST

Outside of health care, most purchasing decisions are based on perceived value: (quality + safety) ÷ cost. Health care decisions historically have not been made this way, in part because of the limited ability of patients and payers to make rational judgments about the quality and safety of a given provider or system, and in part because health care insurance insulates patients from the full cost of care. Much of the recent push to measure and to improve quality and safety should be seen as part of a broader effort to allow patients and payers to make rational judgments about value and to choose their providers on the basis of such judgments. Given the stakes, it is vital for physicians and other health care providers to participate in efforts to measure and improve the quality and safety of care and to do so while being mindful of the price tag.

COMPREHENSIVE CHRONIC DISEASE MANAGEMENT

EDWARD H. WAGNER

Although there is no clear definition of a chronic disease, the term generally refers to long-standing degenerative conditions of noninfectious origin. However, chronic infections, such as HIV or hepatitis C, and many mental and behavioral disorders also last for months, years, or a lifetime. Regardless of cause or pathophysiology, chronic conditions require ongoing attention and adjustments by patients and their loved ones and care by professionals. Patients with a wide variety of chronic health problems have similar needs to minimize morbidity and optimize quality of life (Table 12-1). Because these needs are shared across conditions, clinical management of these seemingly disparate illnesses requires similar practice capacities and functions. For example, the design and organization of care that leads to better outcomes are remarkably similar for diseases as clinically different as diabetes, depression, and HIV.

To live effectively with their health conditions and manage their treatments, patients must have access to the necessary information, skills, and encouragement. They must also receive evidence-based therapy and preventive care to improve disease control and reduce the risk of complications and exacerbations. The severity of most chronic conditions and the effectiveness of ongoing therapy wax and wane over time. As a consequence, regular monitoring and reassessment are required by patients and clinicians alike. When chronically ill patients experience periods of increased severity and risk, they benefit from an intensification of management and support. Care for the chronically ill generally involves multiple health professionals and care settings, for which transitions must be coordinated.

THE GOALS OF CHRONIC CARE MANAGEMENT

The goals of chronic care management are to meet the aforementioned needs of patients with chronic illness routinely and efficiently by delivering care in a system organized to do so. Chronic conditions, whether medical or psychiatric, present very different challenges for patients and their caregivers than do acute illnesses or injuries. Rarely cured and often changing in severity over time, chronic illness necessitates continuous monitoring and adjustments by patients (self-management) and caregivers alike.

The decisions made and behaviors undertaken by patients to deal with their illness, generally called *self-management*, influence the course and outcomes of most chronic diseases in major ways. Patients make decisions and take action in dealing with symptoms, coping with the social and emotional impacts of illness, monitoring their condition, taking medications, adjusting lifestyle, and interacting with the health care system. Most need training and ongoing support from their clinical providers to become competent managers of their health and their illness. The competence and confidence with which patients self-manage their illness have a major impact on outcome. For example, participants in diabetes or hypertension self-management training programs generally experience clinically significant reductions in hemoglobin A_{1c} or blood pressure levels without major changes in drug therapy. Self-management can be enhanced in patients of all socioeconomic

TABLE 12-1 COMMON NEEDS OF PATIENTS WITH CHRONIC ILLNESS

- Support and information that enables patients to be competent self-managers of their health and illness
- Effective clinical and behavioral treatment that keeps the disease under control and optimizes health status
- Effective preventive care to reduce the risk of complications and other morbidity
- Ongoing monitoring of the patient's condition to detect and respond to problems early in their course
- Intensification of management and support during high-risk periods
- Coordination of care to increase the efficiency and effectiveness of referrals and to prevent the mishaps that commonly occur during care transitions

groups by empowering, training, and supporting them. Modern self-management support is a collaborative rather than a didactic process that seeks concordance between providers' and patients' perspectives on the goals of treatment and the actions needed to reach those goals.

Whereas the primary goals of acute disease care are cure and recovery, cure is not an option for most chronic diseases, which are often characterized by slowly progressive deterioration, even with excellent care. Nevertheless, control of the metabolic or physiologic abnormalities or symptoms resulting from the underlying pathophysiologic processes (disease control) is now possible for many chronic conditions. Thus, a major goal for the management of many chronic illnesses is effective clinical treatment in accord with the best scientific evidence. Drugs, lifestyle modification, and other therapies attempt to minimize morbidity, limit further organ damage, reduce the risk of exacerbations and complications, and maintain quality of life and function. The metabolic or physiologic abnormalities or symptoms used to assess disease control often serve as clinical targets to guide therapy and as performance indicators to monitor the progress and quality of care for populations of patients (e.g., the percentage of diabetic patients with blood pressure <130/80 mm Hg). Disease control is best achieved through the systematic use of evidence-based treatment protocols that carefully step up or intensify treatment until clinical targets are reached.

Ongoing monitoring and assessment of chronically ill patients, including ensuring that they are not lost to follow-up, are essential to optimize therapy. Regular assessment of self-management activities reinforces their importance to the patient and to the overall management of the condition. Serious exacerbations and complications of common chronic illnesses are potentially preventable if identified early in their course and treated appropriately (e.g., recurrence of major depression, opportunistic infection in patients with HIV, lower extremity amputation among diabetic patients). The periodicity of assessments must change as the severity of illness waxes and wanes over time.

An increasingly important goal of effective chronic care management is to provide more intensive monitoring and management during periods of high risk, such as transitions from hospital to community or exacerbations. Clinical care or case management by nurses, pharmacists, or other nonphysician health professionals enables closer monitoring of patients, helps with medication adjustment, provides self-management support, and facilitates care coordination. Effective care management programs can reduce the likelihood of rehospitalization for chronically ill patients discharged from the hospital, reduce emergency room visits and hospitalizations among multiproblem ambulatory older adults, and improve disease control.

Chronically ill patients receive medical and supportive services from multiple providers with differing expertise in different settings. Without good coordination, many opportunities exist for errors, inefficiencies, and patient distress. Effective coordination of care can prevent or reduce hospital readmissions because of failures of post-discharge care, failed referrals, referrals without adequate information from the primary care provider, specialty visits without communication back to the primary care provider, duplicated testing, and so forth. Without assistance from their primary providers, patients or their loved ones must often assume responsibility for the onerous task of coordinating care.

MATCHING PATIENT NEEDS AND CARE DELIVERY

Outpatients with diseases such as diabetes, hypertension, and major depression have been estimated to receive evidence-based interventions only about half the time, and less than half achieve optimal disease control. When individual practices are audited, omissions of evidence-based care appear almost randomly across different interventions and among patients within a practice, suggesting that these omissions are related to flaws in care systems rather than cognitive gaps.

The other goals of chronic care management are met even less often, because ambulatory care systems are largely organized to react to acute problems, not to address the ongoing needs of the chronically ill. The focus on making a diagnosis and initiating treatment for the problem at hand leaves little time for addressing less urgent needs such as medication adjustment, self-management support, and preventive care. Reimbursement systems that favor multiple short encounters aggravate the problem.

Lack of attention to patient self-management and inappropriate drug management by clinicians or patients are largely responsible for the poor control of chronic illness. Abundant evidence indicates that adherence to evidence-based treatment protocols substantially increases the proportion of patients reaching therapeutic targets and reduces the risk of morbidity and mortality. The protocols for most chronic conditions include recommendations to step up or intensify therapy when clinical targets are not reached. Failure to intensify treatment in patients who have not achieved therapeutic targets, called *clinical inertia*, has been found in a large percentage of patients with uncontrolled diabetes, hypertension, depression, and other chronic illnesses. Clinicians have an understandable reluctance to increase drug doses or add new drugs, but concerns about toxicity or patient nonadherence can be mitigated if practices have organized approaches to stepping up therapy and monitoring its impact.

Deficiencies in practice infrastructure and the professional environment compound the difficulties of meeting the needs of chronically ill patients. The majority of ambulatory practices in North America still has no electronic clinical record system, performance measurement program, or access to colleagues trained to provide self-management support or clinical care management. Primary care physicians are increasingly uninvolved or even unaware when their patients are hospitalized. Specialists' communications with and support of primary care practitioners have deteriorated because of complex provider network requirements. Efforts to improve the quality of chronic care must focus on improving the infrastructure and practice systems that busy clinicians require to meet the needs of their patients.

Interventions That Improve Care and Outcomes of Chronic Diseases

A wide array of interventions can improve the care and outcomes of major chronic diseases by changing the organization and functioning of the care delivery system, regardless of the specific condition. These changes fall into four general categories. *Patient-directed interventions* try to change patient knowledge, increase their involvement in care, and alter their behavior. *Provider-directed interventions* give providers feedback about the quality of their care and aim to change providers' knowledge and behavior through education and reminders. *Organizational changes* generally focus on the composition and functioning of the care team and the organization of office visits (e.g., group visits) and other encounters (e.g., telephone management). *Information technology (IT) interventions* include the use of computer reminders and other decision support programs, as well as the use of registries for population and patient management. Growing evidence suggests that the use of registries to measure performance, identify individuals needing care, and plan individual patient care may be the IT function that contributes the most to improving the care of the chronically ill.

Provider-directed interventions, especially educational programs, generally demonstrate weak effects. Conversely, interventions that change the composition or functioning of the practice team have the most salutary effects.[2,3] Across conditions, assigning patient care responsibilities to the nonphysician members of practice teams leads to the greatest improvements in disease control and other outcomes. Better informed patients have better outcomes when they receive care from more informed providers who are supported by a well-organized clinical team and appropriate IT.

The Chronic Care Model

The chronic care model identifies features of a health care system that encourage high-quality chronic disease care: self-management support, delivery system design, decision support, clinical information systems, health care organization, and community resources. Evidence-based changes in these six areas foster productive interactions between informed patients, who take an active part in their care, and providers with resources and expertise.[4]

This approach presumes that patients with one or more chronic illnesses have a primary care clinician who assumes responsibility for managing their care and coordinating the activities of other clinicians and institutions that provide advice and services. It posits that important patient outcomes, such as the prevention of morbidity, mortality, and avoidable emergency room visits and hospitalizations, can be affected by productive medical care.

Productive interactions are more likely to occur when patients actively participate in their care. To do so, patients need to be informed—that is, they must have the relevant information and skills to manage their illness. Patients also must be empowered to take an active role in their health care. More active patients are more likely to engage in relevant self-management behaviors and to use health care more effectively. A number of group and individual interventions increase the likelihood that patients have sufficient understanding of their illness and its treatment and the skills and confidence to be competent self-managers.

The other partner in productive interactions is the primary care clinician and the practice team. Before visits with chronically ill patients, practice teams should review accessible information to determine what services are needed, have clear assignments or standing orders for the delivery of those services, and include staff trained to perform them. Although all six elements of the chronic care model contribute to a delivery system that can effectively manage chronic illness, changes in two categories—delivery system design and self-management support—are essential to improve disease control and reduce morbidity and mortality.

Self-Management Support

Didactic patient education alone has been demonstrated to have little if any impact on patient behavior or disease control. To change their lifestyle, take medications as directed, deal with symptoms and stress, and address the other challenges of living with chronic illness, patients need to participate actively in their care, understand and agree with the clinician's assessment of the problems and recommendations, learn the skills needed to carry out the recommendations, develop goals and an action plan to guide behavior change, and review their progress regularly with the primary care team.

These needs can be met in either group or individual sessions that involve skill building, discussion, and negotiation related to recommendations, goals, barriers to reaching goals, and actions to overcome barriers. Although self-management courses facilitated by peer or professional leaders improve disease control in diabetes, hypertension, and other chronic diseases, their effects diminish after termination of the program. Sustained follow-up and reinforcement are essential.

Sustained self-management support is best accomplished by the primary care team in the context of ongoing chronic illness care. Although a physician's advice and encouragement are important, most primary care clinicians have neither the time nor the training to help patients set behavioral goals and develop action plans and then follow up by telephone or e-mail. Clinical staff such as nurses or medical assistants with good communication skills and additional training in counseling methods can and should perform these functions.

Delivery System Design

Team Care

The goal of delivery system design is to match the organization of care delivery to the needs of the chronically ill. Without the help of a team, it is unlikely that, in the course of a 15- to 20-minute visit, physicians can manage intercurrent problems, review and adjust treatment, provide recommended assessments and preventive care, discuss self-management goals and plans, and plan follow-up. Designing effective team care begins with a consideration of the various tasks required to meet the needs of the chronically ill and ensure adherence to guidelines. Some of these tasks, such as self-management counseling or medication reconciliation, are generic; others are disease specific. Key tasks are allocated to the most appropriate members of the practice team. The team's routine involvement in patient visits is facilitated by protocols and/or standing orders that guide independent action by nonclinician staff. Brief meetings, often termed *huddles*, before clinic sessions allow practice teams to review key data (often from registries) on scheduled patients to identify and plan the delivery of needed services. The goal is to maximize the productivity of every patient interaction.

Planned Interactions

Much of chronic care management involves predictable preventive care or disease management activities, which are often postponed when chronically ill patients initiate care for an acute problem. The availability of key patient data gives practice teams the opportunity to update chronic illness care even during visits for more urgent problems. Practice-initiated planned visits can focus on patients who are noncompliant with guidelines, have failed to reach treatment targets, or have been lost to follow-up. The practice tries to schedule longer visits that are structured to address these patients' needs. Another format for the delivery of planned care is the group visit, in which patients receive their primary medical care together as a group. Group sessions generally include the same check-in assessments that occur during an individual visit, followed by brief individual communications between the primary care provider and each patient, opportunities for private consultations, and an educational session with ample opportunity for peer-to-peer interaction. Approximately 30 to 50% of patients offered group visits attend them, and many prefer to receive much of their care in this setting.

Follow-up and Case Management

Follow-up tailored to a patient's needs and the clinical severity of the disease is a critical component of effective chronic care management. Traditionally, follow-up consists of periodic in-person physician visits whose frequency is limited by cost and convenience. Chronically ill individuals often experience periods when more intensive monitoring would be helpful, such as during exacerbations or intercurrent illnesses, following hospital discharge, or while medications are being changed. Ample evidence indicates that follow-up by telephone, e-mail, or telemedicine can be cost-effective and far more flexible than face-to-face return visits. Nonphysician team members, guided by protocols with clear referral criteria, can effectively manage electronic follow-up. Self-monitoring by patients is an important component of the follow-up plans for many chronic illnesses and is especially useful when patients use the results to adjust their therapy as well as to inform their practice team. Collecting self-monitoring data for the sole purpose of bringing them to the doctor's office appears to be far less effective. A small number of chronically ill patients at high risk of hospitalization, nursing home placement, major complication, or death need even more intensive clinical case management services. Clinical case management appears to be effective for chronically ill patients discharged from the hospital; multiproblem, high-risk older patients in community practice; high-risk patients with type 2 diabetes and other diseases; and patients with major depression and other chronic psychiatric disorders.

Disease management programs have proliferated over the past decade. These generally involve nurse case managers who have limited if any involvement with the patients' physicians or their medical care. This disconnected case management system is relatively ineffective unless the case manager collaborates closely with the primary care clinician, influences the medication regimen directly or indirectly, and reviews his or her caseload regularly with the relevant medical specialist.

Decision Support

Efforts to educate health professionals have a very limited impact on clinical performance when compared with inserting information and alerts directly into the flow of decision making. Even the most carefully developed evidence-based guidelines will have no impact on practice if they are not integrated into clinical management through computer templates, alerts, protocols, standing orders, and other efforts to standardize practice.

Many chronically ill patients who are cared for by generalists benefit from the advice and involvement of medical specialists. Communication channels between generalists and specialists (Chapter 438) can be improved by creating systems whereby consultants respond to questions in real time by secure messaging within an electronic medical record system or by reviewing the caseloads of nurse care managers.

Involving patients in decision making improves patient satisfaction with their treatment, adherence with therapy, and even some health outcomes. To support their increasing role, a wide array of decision aids has been developed for patients.

Clinical Information Systems

Well-maintained registries that are either independent or incorporated in an electronic medical record enable practices to identify patients who need additional services, produce rapid summaries of key clinical data and services for future patient encounters, and measure clinical performance. Registries allow practices to both monitor and manage their chronically ill populations. For example, individuals overdue for important preventive interventions or who fail to keep appointments can be efficiently identified and contacted.

Electronic two-way communication between patients and providers is playing an increasing role in the management of chronic disease. Telehealth and web portals enable providers to obtain and respond to clinical data from patients, and they give patients an efficient mechanism for addressing their questions and concerns.

Community Resources

Programs and organizations in patients' local communities can most effectively meet many of their needs. Such needs include transportation, homemaker services, smoking cessation (Chapter 31), exercise (Chapter 15), weight control (Chapter 227), peer support, caregiver support and respite, self-management training, and financial counseling and assistance. For commonly needed services, practices should at least be able to provide information to advise patients on their best options.

TRANSFORMING PRACTICE

Measures of disease control and other indicators of the quality of chronic care begin to improve only when practices have made system-wide changes in most of the elements of the chronic care model, such that the routine care of all their chronically ill patients has been affected. Practice routines and culture must change in ways that are initially foreign and uncomfortable for many practitioners. Team care means more meetings, new roles, and additional training for staff. To have useful registries and provide proactive care, busy practices must define their patient population and learn to manipulate software and data to get the information they need. Some of the changes may require additional financial investment. For all these reasons and more, improving chronic care management requires highly motivated physicians and practices that actively engage in continuous quality improvement. Practices must develop approaches that fit their patient population, resources, and practice style, and they must refine and adapt them using rapid cycle improvement methods.

Health Care Organization

Many practices caring for chronically ill individuals are parts of larger health care organizations that can either encourage and promote the improvement of chronic care or undermine and obstruct it. Helpful organizations promote continuous quality improvement, incorporate a trusted performance measurement system, and provide financial and/or nonfinancial incentives for high quality.

COUNSELING FOR BEHAVIOR CHANGE

F. DANIEL DUFFY

Most office visits end with a brief conversation about diagnosis and a treatment recommendation, often including changes in long-standing behaviors. For clinicians, these conversations are routine, but for patients, these recommendations may challenge long-standing beliefs about well-being and begin repeated cycles of success and failure in replacing unhealthy habits with healthy ones. For patients with chronic illness, these habits typically include daily monitoring and medications for life.

Behavior change counseling is interpersonal therapy that changes mental models of health and internal motivational systems to reward healthy habits and extinguish unhealthy ones. The theory of behavior change counseling is grounded in cognitive behavior therapy, person-centered therapy, and social cognitive theory. Under experimental conditions and in practice, behavior change counseling delivered by trained counselors is efficacious in sustaining healthy diets, physical activity, abstinence from smoking, reduced alcohol consumption, safer sex, and daily self-care routines including adherence to medications.[1] The translation of behavior change counseling into a brief outpatient visit is challenging, owing to the long intervals between visits and the limited funding for counseling. Limited empirical evidence shows that brief office-based counseling using tailored patient-centered motivational methods and performed by trained clinicians successfully reduces smoking[2] and the hazardous use of alcohol.[3] Modest success can be achieved with brief office-based behavior change counseling for medication adherence, adopting safer sexual practices, making dietary change, and initiating physical activity.[4] The combination of direct counseling by the physician and a prepared office staff that supports patient self-care produces more effective outcomes. At a minimum, patient-centered motivational counseling improves the satisfaction of patients and physicians, forges therapeutic relationships, and influences modest changes in patients' health habits.

MODEL FOR OFFICE-BASED BEHAVIORAL CHANGE COUNSELING

Efficient behavior change counseling can be organized according to the transtheoretical model of change (Fig. 13-1), which cycles through five cognitive-experiential stages (*precontemplation*, *contemplation*, *determination*, *action*, and *maintenance*) and often through a sixth stage (*relapse*). Many patients recycle through the stages several times before establishing a new behavioral habit.

By identifying the stage of change, physicians can select efficient counseling strategies. For those who are not ready to change (precontemplation and contemplation), advice, education, and motivational counseling work best (Table 13-1). For those who are ready (determination and action), cognitive behavioral counseling based on self-determination theory works. For those who are already changing (maintenance and relapse), interventions based on social cognitive theory provides a good approach. An adaptation of the Counseling and Behavioral Interventions Work Group of the U.S. Preventive Services Task Force's "5 As" (assess, advise, agree, assist, and arrange) guides behavior change counseling in general health care settings.

Assess Risk for Unhealthy Behaviors

While taking a history of chronic illnesses (Chapter 6), physicians should ask about self-monitoring, adherence with medications, and self-care barriers and their solutions. In the personal and social history, physicians should ask about tobacco use, alcohol drinking, physical activity, diet, and sexual risks. In the family history, physicians uncover genetic and familial risks. Review of a patient's self-administered questionnaire by trained staff can help the physician obtain a health risk assessment efficiently.

Advise to Change Unhealthy Behaviors and Adopt Healthy Ones

There is strong evidence that direct, clear, nonjudgmental, and tailored advice delivered by a personal physician during a short office visit can help some patients stop smoking or reduce hazardous drinking.[5] Unfortunately, data also show that physicians rarely deliver information or advice about risky behaviors, unless behavior change is the specific agenda for an encounter or treatment for a condition.

If the patient expresses interest and time permits, physicians should give personalized advice. If time is short, the physician should arrange a counseling conversation for the near future. How advice is given influences internal motivation and self-efficacy. For example, asking permission before giving advice and postponing the conversation if the patient declines demonstrate respect for patient autonomy and acknowledge that motivation to change is entirely an internal process.

If the patient agrees, the clinician begins not by giving information about behaviors and risk, but by asking the patient to share his or her values and beliefs about the unhealthy behavior. Asking "*What do you like most about … ?*" followed by, "*What concerns you about … ?*" changes the focus of behavior change counseling from a treatment to an understanding of patients' values and beliefs. The ensuing conversation should explore the patient's perceived advantages of continuing behaviors, thoughts about changing, and confidence in the ability to do so. The physician adds information to the conversation, often by asking probing questions. This technique creates an opportunity to empathize with patients' conflict and deliberately raise their conviction that changing is important for achieving valued personal goals and enhancing self-confidence in the ability to do so.

Based on the conversation, clinicians diagnose the patient's stage of change in order to agree on goals for progressing through the cycle of change. A diagnostic tool, the *Conviction-Confidence Ruler* (Fig. 13-2), helps assess internal motivation for change. The number patients select suggests their stage of change.

Patients who select a low (0 to 2) conviction and confidence number are in the precontemplation stage. If they select low conviction and confidence scores, express ambivalence or emotional distress about advice to change, and do not intend to change soon, they are in the contemplation stage.

Patients who select a midrange conviction and confidence score (3 to 7) and state their intention to change within the next month may be in the determination stage. When they select a high conviction (8 to 10) and moderate to high confidence number (5 to 9) or report already making attempts at change, they are in the action stage.

Maintenance-stage patients select high conviction and confidence numbers. They report successful experience with the healthy behavior and effective coping in response to situations in which the unhealthy behavior appears attractive or safe to do just once more. In the relapse stage, patients reported a period of success with a new behavior but then regressed. Feelings of low self-efficacy and unrealistic expectation for positive benefits from the old behavior win over their intention to maintain the change. Disappointed and discouraged, such patients select a low confidence number. If not demoralized, they select a high conviction number; otherwise their conviction number is also low, as they recycle back into resistant precontemplation.

Agree on Appropriate Goals for the Stage of Change

In this step, physicians elicit and clarify patients' self-determined goals, articulate their own goals, and find common ground or negotiate a compromise. The result is agreement on clear, realistic, and achievable goals appropriate for the patient's stage of change (Table 13-2). Unfortunately, such agreement on goals is infrequent after usual medical encounters. Few patients are in the determination or action stages, so using only action-based behavior change counseling is often ineffective and frustrating. Patients who are in the precontemplation or contemplation stages and not ready for a change goal can agree to learn more. Most patients are in maintenance or relapse stages, with experience with both success and failure; counseling that supports self-regulation is most effective and efficient in such situations.

Assist Patient in Developing a Self-Determined and Stage-Appropriate Plan

The assist step involves stage-specific counseling, which may require training to be effective. When physicians have insufficient time or training, they can refer patients to behavior change counseling professionals, either within the practice or elsewhere in the community.

Counseling patients in the precontemplation stage raises their personal conviction that change is necessary to achieve their life and health goals. This counseling elicits the patient's commitment to seek information from family members, friends, or people who have successfully made similar changes about the behavior and what changing might be like. This cognitive, attitudinal, and emotional exploration clarifies the internal conflict between current

TABLE 13-1 STAGES OF CHANGE CHARACTERISTICS

STAGE OF CHANGE	PATIENT RESPONSE	PATIENT COPING TASKS	CLINICIAN COUNSELING TASKS	COUNSELING RESOURCES
Precontemplation	Surprise Not thinking about changing Demoralized if had relapse	Learn about risks of behavior Develop self-awareness	Reflect Advise Inform	Information media Self-assessment logs or diary
Contemplation	Ambivalence Gives reasons for concern about behavior Gives rationalization for unconcern about behavior	Emotional disturbance Self-re-evaluation Raise conviction Raise confidence	Empathize with patient's ambivalence Avoid argument Develop discrepancy Roll with resistance	Conviction-Confidence Ruler Decisional balance Feedback logs Role models Referral for group training
Determination	I must change I can do it	Raise conviction Raise confidence Develop action plan Pick start date Go public	Support self-efficacy Negotiate action plan Anticipate problems Connect to social support	Menu of options Referral for formal counseling List of role models
Action	What will I do? Who or what might help? What problems might I have?	Take action steps to change Manage withdrawal from addiction	Manage cues to old behavior Alert to consequence of new behavior Add rewards Manage withdrawal	Written plan Menu of cues Menu of consequences Menu of rewards Referral for counseling
Maintenance	Satisfied with changed self Spontaneously tells about success and difficulties	Manage cues to old behavior Manage bad effects of the new behavior Seek and use social support Become a role model to others	Discuss signs and times of relapse danger Discuss the danger of "relapse thinking" Admire new lifestyle habits	Role-model for others Frequent social support Referral for maintenance counseling
Relapse	Tells about thinking old behavior was no longer a concern Loss of control Demoralization	Learn the antecedents of relapse Recognize "relapse thinking" Keep public Call for help	Reframe relapse to be a valuable lesson Evoke self-efficiency Move quickly back into action	Referral for formal relapse counseling Contact list of recovery role models Frequent follow-up

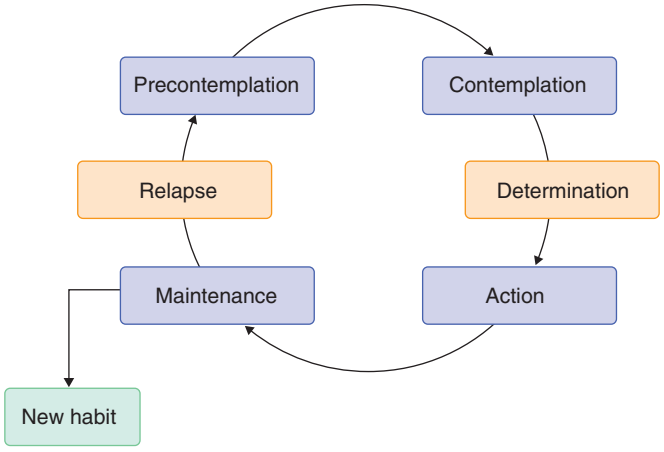

FIGURE 13-1. Cycle of change stages.

TABLE 13-2 SUGGESTED GOALS FOR EACH STAGE OF CHANGE

STAGE OF CHANGE	EXAMPLE GOALS FOR VITAL BEHAVIORS
Precontemplation	Learn about the risk of continuing unhealthy behavior
Contemplation	Re-evaluate one's life's goals in context of unhealthy behavior
Determination/action	Commit to a start/quit date and begin vital behaviors
Maintenance	Self-monitor behavior, success, and learning
Relapse recovery	Intensify social support and self-regulating behavior

Conviction–Confidence Ruler

On a scale of 1–10, how *convinced* are you that it is important for you to change … *(Name the behavior)* … ?"

Not at all convinced 0 1 2 3 4 5 6 7 8 9 10 Totally convinced

On a scale of 1–10, how *confident* are you that you have the ability to change … *(Name the behavior)* … ?"

Not at all confident 0 1 2 3 4 5 6 7 8 9 10 Totally confident

FIGURE 13-2. Motivational counseling aid.

behavior and life goals or moral values. Precontemplation is not influenced by professional argument or debate.

Motivational interviewing, which is best delivered during visits specifically scheduled for behavior change counseling, is effective for patients in contemplation, especially for those with addiction. Motivational interviewing helps patients explore and resolve their ambivalence about changing. Using open-ended questions such as "*What do you like about … (the unhealthy behavior)…?*" physicians inquire with genuine interest to reveal the patient's perceived advantages of the unhealthy habit or behavior. Turning to the healthy behavior, the physician asks with interest "*What concerns you about doing … ?*" to clarify what patients believe the risks and the benefits of adopting vital behaviors might be. A *decisional balance table* (Table 13-3) can display patients' reasons for maintaining the current behavior compared with those for adopting the healthy one. Counselors should listen to patients' statements, repeating the exact words to elicit their self-motivating statements. By guiding patients in examining both sides of their ambivalence, resistance can be reduced and readiness to change can be assessed, without attempting premature change.

By helping patients "think out loud" about their conflicting reasons for change and their rationalizations for not changing, motivational interviewing amplifies the discomfort of ambivalence and motivates change. For example,

TABLE 13-3 DECISIONAL BALANCE

BEHAVIOR	REASONS NOT TO CHANGE	REASONS TO CHANGE
Unhealthy behavior	What do you like about it?	What are your concerns about it?
Healthy behavior	What are your concerns about it?	What do you like about it?

a conviction-confidence scale can clarify a patient's values and knowledge about the behavior, thereby allowing the counselor to ask, "*Why 4 and not lower*?" Asking questions like "*What would it take to raise your conviction level?*" helps patients to voice their values and beliefs and to understand their strengths and resources.

When patients express resistance to change, motivational interviewing recommends that counselors not argue but rather make empathic statements to demonstrate their understanding of the patient's painful ambivalence, beliefs, and feelings that rationalize a low conviction about the benefits of change. Using the conviction-confidence ruler, physicians can engage a patient's self-reflection by asking, *"What makes your commitment or confidence a "2" and not "0"?* If patients report a zero for commitment or confidence, the counselor might ask, *"Zero … that's as low as you can get….What would have to happen to make it a 1?"*

Determination/action counseling uses cognitive-behavioral methods to help patients develop a written plan to change lifestyle behaviors and to add self-monitoring and coping strategies to prevent relapse. The plan, which identifies the new behaviors patients will adopt to replace unhealthy ones, includes changing social situations that stimulate craving for the effects of the old behavior and using reminders and rewards for performing the new behavior. When the change requires an end to addictive behaviors, the plan must include treatments to manage withdrawal and craving. The plan asks partners and others who are making similar changes for support. The counseling helps patients anticipate challenges to sustaining the change and develop coping solutions for preventing and recovering from lapses. Plans work best when patients identify the people, resources, and coping strategies themselves. Exploring past experience with change may help identify strategies that were at least temporarily successful. Conversely, identifying what went wrong following a period of success clarifies how to cope with relapse situations.

Multidisciplinary teams of nurse educators, nutritionists, physical therapists, psychologists, and pharmacists can share education, counseling, and skills training. Referral is usually necessary for changing addictive behaviors and self-management of chronic illness.

The maintenance stage requires counseling in coping strategies to deal with the attraction or perceived safety of the unhealthy behavior, especially during the first months of change. Counseling aims at enhancing coping responses by self-monitoring of the positive effects of the healthy behavior, avoiding situations in which the unhealthy behavior becomes more attractive, and developing a strong social network that supports new coping responses.

Maintenance counseling conversations explore successes using questions like *"What has worked?"* and lapses using questions like *"Most people have difficulty; how has this change gone for you?"* It is useful to ask specifically about relapse thinking: *"Many people begin to think that after a while it's safe to … (return to the old habit) just one more time; how have you handled such thoughts?"* Regarding engaging social support, counselors might ask, *"Who or what has helped you sustain your new behavior?"* Planning for lapse recovery can be initiated by asking, *"Should you slip, what will you do, or who will you call?"*

If relapse occurs, counselors should remind patients that relapse, by definition, follows success, which proves that change is possible. Relapse must become a learning opportunity to revisit pre-relapse thinking and develop a new action plan.

Arrange Follow-up and Referral for Formal Counseling

At the conclusion of counseling, counselors ask patients to rehearse the plan verbally and state their confidence in being able to execute it. Confidence ratings less than 7 may be insufficient to undertake and sustain vital behaviors. Arranging for counseling at a future date aims to identify and resolve barriers until a patient's confidence level is at least 7, or to renegotiate a goal, with a confidence level of at least 7.

The arrange step involves scheduling future office visits within an appropriate interval for the stage of change. Longer counseling visits within a few months are appropriate for the precontemplation and contemplation stages. In-person or telephone follow-up visits within a week or two are useful for counseling in the determination/action stage. For the maintenance stage, office follow-up counseling is as frequent as possible, usually monthly, and ideally combined with almost daily contact with other supporting persons or role models. When intensive counseling is necessary, counselors may arrange referral to patient education classes, behavioral counseling professionals, or self-help support groups to monitor the effectiveness of the referred behavior change counseling.

THE PERIODIC HEALTH EXAMINATION

DAVID ATKINS AND MARY BARTON

Primary and secondary prevention is an essential part of primary care and the patient-centered medical home (Chapter 12). The appropriate services and their frequency vary with the age, gender, and individual risk factors of each patient. A periodic health examination focusing on prevention increases the delivery of appropriate screening and lifestyle counseling. The most comprehensive prevention recommendations are produced by the U.S. Preventive Services Task Force (USPSTF), an ongoing panel of experts supported by the federal Agency for Healthcare Research and Quality (*http://www.uspreventiveservicestaskforce.org*).

USPSTF recommendations are used by major primary care subspecialty groups, many health plans, and quality organizations. The USPSTF bases its recommendations on two factors: an estimate of the *net benefits* (benefits minus harms) of a service, and an assessment of the *certainty* of that estimate, based on the rigor of supporting studies. Grade A recommendations require high certainty of a substantial net benefit, most often from large, prospective, controlled studies that measure morbidity or mortality. USPSTF recommendations are thus more conservative than those of some subspecialty organizations that may give more weight to indirect evidence, such as earlier detection of disease, and less weight to potential harms of interventions. Clinicians can draw several general conclusions from an evidence-based approach to prevention: we should be selective in our use of screening tests and involve patients in decisions about specific services for which a small chance of benefit must be balanced against possible harm.

HISTORY AND RISK ASSESSMENT

The history and risk assessment are important tools to identify individuals who may need additional screening tests or immunizations not generally recommended for their age group or who may benefit from specific counseling to address unhealthy behaviors. Formal health risk appraisals should be linked to a system to provide specific feedback and targeted interventions. Risk assessment should address the following:

- Use of tobacco, alcohol, and other drugs (especially injection drugs) (Chapters 31, 32, and 33)
- Diet (Chapter 220)
- Physical activity (Chapter 15)

- Sexual behavior that may increase the risk of sexually transmitted diseases or unintended pregnancy (Chapters 293, 392, and 395)
- Family history of cancer and heart disease
- Residence (community risk of infectious diseases)
- Presence of chronic diseases, such as diabetes, and of other cardiovascular risk factors (Chapter 51)

SCREENING FOR EARLY DISEASE OR ASYMPTOMATIC RISK FACTORS

Every year, new screening tests are introduced and marketed on the basis of their ability to detect unrecognized diseases or risk factors for disease. Other conditions need to be fulfilled for a screening test to be worthwhile for routine use, however (Table 14-1). Benefits of screening must be balanced against the potential harms, including false-positive results and the risks and costs of follow-up procedures or treatments. Even when tests have high specificity, the majority of positive results will be false-positives if the test is used to screen healthy populations for uncommon conditions such as cancer (Chapter 9). There is growing evidence that cancer screening can lead to "overdiagnosis"—detection of slow-growing cancers that would never have caused clinical symptoms in a patient's lifetime. Overdiagnosis subjects patients to the side effects of treatment with no benefits. A relatively small number of screening tests have been proved beneficial for the general population (Table 14-2), but additional tests are indicated for specific populations at risk (Table 14-3). Many commonly used tests are not recommended by the USPSTF (Table 14-4) because they provide little benefit or lack sufficient evidence to prove or disprove their value.

Depression

Depression is common and frequently undetected in primary care (Chapter 404). Simple screening instruments, including the following two questions—During the past 2 weeks, have you felt down, depressed, or hopeless? During the past 2 weeks, have you felt little interest or pleasure in doing things?—increase the detection of major depression. To improve outcomes, however, screening for depression must be linked to an organized system with staff support to ensure follow-up and treatment.■

High Blood Pressure, Abnormal Lipids, and Other Coronary Risk Factors

Blood pressure should be measured at least every 2 years (Chapter 67). The USPSTF recommends measuring total and high-density lipoprotein cholesterol, which can be done on fasting or nonfasting samples, beginning in middle age or earlier in the presence of other cardiovascular risk factors. The National Cholesterol Education Program guidelines recommend fasting lipoprotein analysis beginning at age 20 years (Chapter 213). Either strategy will detect the high-risk patients who need lipid-lowering therapy. Treatment decisions for elevated lipids and for blood pressure should be based on estimates of coronary heart disease risk (Chapter 51). Although factors such as C-reactive protein, homocysteine, and coronary calcification as assessed by computed tomography (CT) are associated with an increased risk of heart disease, the USPSTF found insufficient evidence to recommend their routine use.■

Abdominal Aortic Aneurysm

Between 5 and 9% of men older than 65 years have an abdominal aortic aneurysm (Chapter 78). The risk of aneurysm is higher in smokers and is substantially lower in women. The USPSTF recommends one-time screening with ultrasound examination in men aged 65 to 75 years who are current or former smokers, based on trials demonstrating as much as a 40% lower death rate from abdominal aortic aneurysm rupture in screened men.■

Colorectal Cancer

Screening can reduce both the incidence of and mortality from colorectal cancer. Options for screening men and women older than 50 years include an annual fecal occult blood test or fecal immunochemical test, flexible sigmoidoscopy every 5 to 10 years, or colonoscopy every 10 years (Chapter 199). Colonoscopy combines detection with the opportunity for biopsy and removal of lesions, so it is preferred in some guidelines. It carries higher costs and risks, however, and no single strategy has proved to be more effective or cost-effective than the alternatives.■ In a randomized trial, a single flexible sigmoidoscopy screening between 55 and 64 years of age reduced the colorectal cancer incidence by 33% and the colorectal cancer mortality by 43% after 11 years of follow-up in people who were screened.■ Evidence is not yet sufficient to support newer technologies such as CT colography or fecal tests for DNA markers of neoplasia. The USPSTF recommends stopping routine screening at age 75 years.

TABLE 14-1 REQUIREMENTS OF AN EFFECTIVE SCREENING TEST

The disease being screened for is an important cause of morbidity and mortality
Screening can detect disease in an early, presymptomatic phase
Screening and treatment of patients with early disease or risk factors produce better health outcomes than does treatment of patients when they present with symptoms
Screening test is acceptable to patients and clinicians—safe, convenient, acceptable false-positive rate, acceptable costs
Benefits of early detection and treatment are sufficient to justify potential harms and costs of screening

TABLE 14-2 PREVENTION RECOMMENDATIONS FOR THE GENERAL POPULATION: FROM THE U.S. PREVENTIVE SERVICES TASK FORCE AND OTHER SOURCES

SCREENING
Height, weight, and body mass index (BMI) calculation: periodically
Blood pressure: at least every 2 yr
Screen for problem drinking
Brief screen for depression*
Total blood cholesterol and HDL cholesterol: every 5 yr for men and women ≥20 yr with CHD risk factors and men ≥35 yr without CHD risk factors
Colorectal cancer screening: age ≥50 yr (see text for options)
Mammogram (± clinical breast examination): at least every 2 yr for women ≥50 yr; discuss with women 40–49
Papanicolaou (Pap) test: at least every 3 yr for sexually active women aged 21–65 yr
Chlamydia: sexually active women ≤24 yr and older women at risk
Bone mineral density test: women ≥65 yr and high-risk women <65 yr
COUNSELING
Substance use
Tobacco cessation
Reduction of risky or harmful alcohol use
Diet and exercise
Limit saturated fat; maintain calorie balance; emphasize grains, fruits, and vegetables‡
Regular physical activity†
Sexual behavior
Unintended pregnancy: contraception
STD prevention: avoid high-risk behavior, use condoms or female barrier with spermicide†
Injury prevention
Lap and shoulder belts
Motorcycle, bicycle, and ATV helmets†
Smoke detector†
Dental health
Regular visits to dental care provider†
Floss, brush with fluoride toothpaste daily†
IMMUNIZATIONS
Pneumococcal vaccine (once, age ≥65 yr)
Influenza vaccine (annual, age ≥50 yr)
Tetanus-diphtheria (Td) boosters (every 10 yr)
Measles, mumps, rubella (MMR) vaccine (susceptible adults aged 19–49 yr)§
Varicella (2 doses, susceptible adults aged 30–49 yr)§
Human papillomavirus (HPV) vaccine (3 doses, women ≤26 yr)
CHEMOPREVENTION
Multivitamin with folic acid (women planning or capable of pregnancy)
Discuss benefits and harms of aspirin to prevent vascular disease in middle-aged adults and others at increased risk of vascular disease

*Depression screening is most effective where systems exist to improve its management.
†The ability of clinician counseling to influence this behavior is uncertain.
‡Diet counseling is most effective when it targets at-risk groups.
§Immunity can be verified by serologic testing, documented history of illness, or vaccination.
Other sources for Tables 14-2 and 14-3 include U.S. Department of Health and Human Services (diet, physical activity) and Centers for Disease Control and Prevention (injury prevention, immunizations, PPD).
ATV = all-terrain vehicle; CHD = coronary heart disease; HDL = high-density lipoprotein; STD = sexually transmitted disease.

TABLE 14-3 RECOMMENDED SCREENING AND INTERVENTIONS FOR HIGH-RISK POPULATIONS

POTENTIAL INTERVENTION	POPULATION
Ultrasound examination for abdominal aortic aneurysm	Current or former male smokers aged 65–75 yr
HIV test	High-risk sexual behavior or IV drug use; consider local epidemiology*
Syphilis (RPR/VDRL)	High-risk sexual behavior; consider local epidemiology*
Gonorrhea screen	High-risk sexual behavior; consider local epidemiology*
PPD	Specific immigrant groups, prisoners, HIV patients
Hepatitis B vaccine	Exposure to blood products; IV drug use; high-risk sexual behavior; travelers to high-risk areas
Hepatitis A vaccine	Persons living in or traveling to high-risk areas; institutionalized persons and workers in these institutions; those with certain chronic medical conditions
Meningococcal vaccine	First-year college students in dormitories; military recruits; those with asplenia; travelers to high-risk areas
Varicella vaccine	Adults born after 1980 without evidence of immunity
Breast cancer chemoprevention	Women at increased risk for breast cancer and with low risk of thromboembolic complications
Diabetes screen	Persons with elevated blood pressure

*Routine screening may be indicated in communities or settings where infection is prevalent.
HIV = human immunodeficiency virus; IV = intravenous; PPD = purified protein derivative; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory.

TABLE 14-4 INTERVENTIONS NOT RECOMMENDED FOR ROUTINE USE IN ASYMPTOMATIC AVERAGE-RISK ADULTS*

Resting or exercise electrocardiography or helical CT for asymptomatic coronary disease
Ultrasound examination for asymptomatic carotid artery disease
Chest radiograph
Routine blood tests for anemia
Routine urine tests
Blood tests or ultrasound examination for ovarian cancer
Whole body CT
Brief tests of mental status
Vitamin supplements
Blood test for hepatitis C infection
Blood level of C-reactive protein to predict coronary risk
Prostate-specific antigen for prostate cancer

*These tests are not recommended for routine use because there is insufficient evidence that they improve clinical outcomes or because harms exceed benefits in the general population. Any of the tests may be appropriate for selected patients on the basis of clinical judgment, and some are under investigation for more widespread use.
CT = computed tomography.

Breast Cancer

In large trials, mammography screening (at intervals of 1 to 2 years, with or without clinical breast examination) reduces breast cancer mortality by 15 to 30% (Chapter 204). Most but not all trials suggest that the benefits of screening extend to women in their 40s, but the benefits are smaller and the risks of false-positive results are higher than in women aged 50 to 70 years. ■ No studies provide data on the benefits of screening women aged 75 and older. In a collaborative study, six independent models predicted that an average of 80% of the benefit of mammography could be achieved with biennial rather than annual mammography, whereas national mammography surveillance data indicate that false-positive results and other harms of screening would be reduced by about half if women were screened every other year instead of yearly. Although many cancers are discovered by patients, teaching women to perform breast self-examination increases the likelihood that a woman will undergo further evaluation for an unimportant finding, but it does not improve outcomes. Widespread screening for *BRCA1* or *BRCA2,* inherited mutations that increase the risk for breast cancer, is not recommended, but women with a suggestive family history (multiple first-degree relatives with breast or ovarian cancer) should be referred for genetic counseling.

Cervical Cancer

Papanicolaou (Pap) screening is highly effective in preventing invasive cervical cancer, but many low-risk women in the United States are screened more often than needed. The USPSTF and American College of Obstetrics and Gynecology endorse delaying screening until age 21, screening only every 2 to 3 years instead of annually in women with previous normal test results (Chapter 205), and offering low-risk women the option of discontinuing screening after 65 years of age. Screening is not indicated in women who have undergone a hysterectomy for benign disease. Liquid-based cytology specimens do not improve clinical outcomes significantly, but they allow testing for human papillomavirus (Chapters 205 and 381), which may help in managing borderline Pap smear results, such as atypical squamous cells. Primary screening for human papillomavirus, although sensitive for cervical neoplasia, is not recommended for routine use because it identifies many younger women with transient infection. Whether women who have received the human papillomavirus vaccine (Chapter 17) need less frequent screening is not yet known.

Prostate Cancer

Screening with prostate-specific antigen (PSA) can increase the detection of organ-confined prostate cancer, but two recent large trials provided conflicting results as to whether screening lowers morbidity or mortality from prostate cancer (Chapter 207). An American trial found no benefit of annual PSA testing, but it was hampered by a high rate of screening in the control group. A European study reported that men randomized to screening every 4 years had a 20% lower risk of dying from prostate cancer after 9 years; for each prostate cancer death prevented, 48 additional men were treated for prostate cancer and 1068 men had to undergo screening. Because of the significant morbidity associated with overdiagnosis and overtreatment, including incontinence and impotence, the USPSTF does not recommend routine PSA screening, but the American Cancer Society and some specialty groups recommend discussing PSA screening with men who have a life expectancy of at least 10 years.

Osteoporosis

Tests of bone mineral density can identify men and women with a high risk of fracture due to osteoporosis and who may benefit from medications proved to lower the risk of fracture (Chapter 251). The USPSTF recommends screening for osteoporosis in women older than 65 years or earlier in the presence of risk factors for osteoporosis. The most accurate predictor of risk of hip fracture is bone mineral density of the hip assessed with dual-energy x-ray absorptiometry. A tool developed by the World Health Organization (*http://www.shef.ac.uk/FRAX/*) incorporates bone mineral density and other risk factors, such as age and fracture history, to guide treatment decisions.

Thyroid Disease

Routine thyroid testing occasionally identifies patients with symptomatic but undiagnosed hypothyroidism (Chapter 233), but it more often detects subclinical hypothyroidism, a disorder marked by elevations in thyroid-stimulating hormone with normal levels of free thyroxine. Because the benefits of treating subclinical hypothyroidism remain uncertain, the USPSTF does not recommend routine thyroid testing in the absence of symptoms. Clinicians should be alert to subtle signs of thyroid disease and have a low threshold for testing patients in high-risk groups, including postpartum and postmenopausal women.

Diabetes

Routine screening for diabetes beginning at age 45 years is recommended by some groups, but the USPSTF recommends screening only in patients with elevated blood pressure (Chapter 237). Although tight glucose control can reduce the incidence of microvascular disease, the benefit of early presymptomatic detection on retinopathy, neuropathy, and nephropathy is likely to be small. The benefits of early detection of diabetes are much greater in persons with hypertension because more aggressive treatment of blood pressure in patients with diabetes has been shown to reduce cardiovascular events within 5 years.

HIV Infection

The USPSTF recommends screening for HIV infection in all pregnant women and in adolescents and adults at increased risk. In an effort to reduce the estimated 25% of infected patients who have not yet been diagnosed, however, the Centers for Disease Control and Prevention recommends that all adolescents and adults aged 13 to 64 years have at least one HIV test and annual tests if they are at high risk.

Sexually Transmitted Disease

Screening for chlamydia (Chapter 326) is recommended for all sexually active women ages 24 years and younger and for older women at risk. Nucleic acid amplification tests can be performed on cervical or urine specimens. Early detection can reduce pelvic inflammatory disease (Chapter 293), a risk factor for infertility and ectopic pregnancy. Similar benefits are likely from screening women for gonorrhea (Chapter 307), but the risk of gonorrhea infection is more concentrated in high-risk urban and southeastern rural populations.

Vision and Hearing

Undetected but correctable vision and hearing problems are common in older adults and can be discovered by asking about problems and performing simple tests of visual acuity and hearing. Regular visual acuity testing is recommended for older adults by many organizations, but a large trial did not find any lasting benefits of screening, despite detecting many correctable causes of vision problems.

BEHAVIORAL INTERVENTIONS

Lifestyle factors contribute to a large proportion of preventable deaths in the United States. Brief interventions are effective for some behaviors such as smoking and problem drinking, but changing other behaviors usually requires more intensive approaches. The *5 As* framework—ask, assess, advise, assist, and arrange—which was developed from smoking cessation research, provides a useful framework for counseling (Chapter 13).

Tobacco Use

Brief interventions can produce small but clinically important increases in quit rates among smokers. Effects increase with more intensive counseling and support, including the use of medication (Chapter 31).

Problem Drinking

A variety of screening instruments can detect patients with problems due to alcohol and those with risky patterns of alcohol consumption. Brief interventions can successfully reduce alcohol consumption in at-risk drinkers (Chapter 32).

Diet

Diet counseling can reduce the intake of saturated fat and increase the consumption of fruits and vegetables. Effects are most consistent with more intensive counseling (multiple sessions with trained counselors) and in higher risk patients, such as those with elevated lipid levels (Chapter 220).

Physical Activity

Moderate physical activity reduces the risk of obesity, diabetes, and coronary heart disease, among other benefits. Studies of counseling in the primary care setting, however, have reported inconsistent effects on long-term levels of physical activity (Chapter 15).

Injury Prevention

Motor vehicle injuries are the leading cause of years of potential life lost before age 65 years. In older persons, falls are a leading cause of unintentional injury and can be reduced with targeted interventions (Chapter 24).

IMMUNIZATIONS

Recommendations regarding immunization (see Tables 14-2 and 14-3) are regularly updated by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (*www.cdc.gov/vaccines*) (Chapter 17). Annual influenza immunization is effective in all adults but is most important in those older than 50 years and others at high risk because of chronic conditions or immunodeficiency. Pneumococcal immunization is recommended at least once at age 65 years or after for all adults and for younger adults with asplenia, chronic heart or lung disease, and other immune disorders. Revaccination is not generally recommended unless the initial immunization was before age 65 or the patient has immune-related risk factors. Two doses of varicella vaccine are recommended for all adults born in the United States after 1980 without other evidence of immunity, and one dose of zoster vaccine is recommended for all adults at age 60. Adults should be revaccinated once with the Tdap vaccine (tetanus, diphtheria, acellular pertussis) and every 10 years thereafter with Td, primarily to maintain levels of immunity against diphtheria.

CHEMOPREVENTION

Aspirin, postmenopausal hormone replacement therapy, and breast cancer chemopreventive drugs carry both benefits and risks. Decisions need to consider the likely benefits (which increase with the underlying risk of the disease being prevented), the probability of harm, and the individual preferences of each patient.

Aspirin

In men and women without known vascular disease, aspirin reduces the combined risk of myocardial infarction, stroke, and other serious cardiovascular events by 12%, but it also increases the risk of serious gastrointestinal bleeding and hemorrhagic stroke and does not significantly reduce cardiovascular mortality.■ Individuals and their physicians need to assess whether the benefits, which increase with the risk of vascular disease, outweigh the bleeding risks, which increase with age (Chapter 37).

Chemoprevention of Breast Cancer

Tamoxifen and raloxifene can reduce the incidence of invasive breast cancer by nearly 50% in women at increased risk, but both agents increase risk of thromboembolic events (including stroke) and worsen menopausal symptoms; tamoxifen also increases the risk of endometrial cancer (Chapter 204). The balance of benefits and harm is most favorable in women younger than 60 years who have an increased risk of breast cancer owing to family history.

Postmenopausal Hormone Therapy

Estrogen therapy reduces the risk of fracture, but it increases the risk of thromboembolism and gallbladder disease (Chapter 248). When given with progestin, postmenopausal estrogen modestly increases the risk of heart disease and stroke (primarily in women older than 60), breast cancer, and dementia.■ Hormone replacement therapy is a reasonable option for women with persistent, troublesome menopausal symptoms, but it should not routinely be used for preventive purposes.

Vitamin Supplementation

The USPSTF does not recommend routine vitamin supplementation because multiple large trials have failed to demonstrate the benefits of vitamins A, C, and E or folic acid against heart disease or cancer. Several studies suggested that β-carotene may increase the risk of lung cancer in smokers, and a meta-analysis suggested that folic acid supplementation could increase cancer risk.

FUTURE ISSUES

As the understanding of genetic factors that modify the risk of disease grows, clinicians may eventually be able to target screening, preventive treatments, or lifestyle interventions to those at greatest risk. The value of using currently available tests to screen average-risk individuals is limited by an incomplete understanding of the predictive value of specific genotypes in the general population, the uncertain effect of such information on clinical decisions, and concerns about the possible adverse effects of screening (e.g., anxiety or "labeling," false reassurance, discrimination).

With the current epidemic of obesity in the United States, and its attendant long-term health consequences, effective counseling tools and strategies may be more important in the coming decades than improved screening and early detection tools. Helping patients choose a healthier diet, increase their physical activity, and maintain a healthy weight is difficult, but the lessons of tobacco control over the past 30 years suggest that a combination of consistent clinical counseling and encouragement, complemented by public health messages and community strategies, can have an important health impact.

PHYSICAL ACTIVITY

DAVID M. BUCHNER

DEFINITIONS

Physical activity can be broadly defined as body movement that is produced by skeletal muscles and expends energy. When discussing the health benefits of activity, it is useful to divide body movements into two categories. *Baseline activity* refers to light-intensity activities of daily life, such as standing, walking slowly, and lifting lightweight objects. *Health-enhancing physical activity* is activity that when added to baseline activity produces important health benefits and generally involves the large muscle groups of the body and substantial energy expenditure. Herein, *physical activity* refers to health-enhancing physical activity. *Exercise* refers to the subset of physical activity that involves a structured program to improve physical fitness.

Regular physical activity improves *health-related physical fitness*—the physiologic components of fitness that influence risk of disease, functional limitations, disability, and premature mortality. These components include cardiorespiratory endurance (aerobic capacity); skeletal muscle strength, power, and endurance; body composition and bone strength; and balance, flexibility, and reaction time.

The primary attributes of physical activity are *type* (mode), *frequency, duration,* and *intensity.* Types of physical activity (e.g., walking, swimming, lifting, stretching) are grouped according to their main physiologic effects into well-known categories: *aerobic* (or "cardio"), *muscle strengthening*, *flexibility,* and *balance.* Intensity is the level of effort during activity. For aerobic activity, the *absolute intensity* is measured in metabolic equivalents (METs), with 1 MET being the resting metabolic rate—an oxygen consumption of roughly 3.5 mL/kg/minute. The *relative intensity,* which is the percentage of oxygen uptake (aerobic capacity) reserve required to perform an activity, ranges from 0 to 100%. In practice, the heart rate is used to monitor relative intensity because of the generally linear relationship between heart rate and percentage of oxygen uptake. The *volume* (or amount) of activity is the product of frequency, duration, and intensity. Volume can be measured as activity-related energy expenditure (e.g., kcal/week) or as MET-minutes per week (a sum of the MET intensity of all activities multiplied by the minutes each activity is performed).

EPIDEMIOLOGY

Levels of Physical Activity

Data on long-term trends in the level of physical activity among adults are limited. Even so, it is highly likely that Americans' level of physical activity has declined since the 1950s. Levels of activity around the home, work-related activity, and transportation activity have apparently declined over the past 50 years. Trends in leisure-time physical activity are either stable or slightly improving.

In recent national surveys that track domestic, leisure-time, and transportation physical activity using questionnaires, about 45% of American adults are active at recommended levels. Using objective measurements (an accelerometer), however, less than 5% of adults meet the recommended levels of physical activity, suggesting that the lack of physical activity is a larger public health problem than previously realized.

Physical activity levels decline with age, and men report more activity than women. Higher levels of income and education are associated with greater physical activity. White Americans report higher levels of physical activity than other racial and ethnic groups do.

Preventive Health Benefits in Adults

There is strong evidence that regular moderate or vigorous physical activity (Table 15-1) reduces the risk for premature mortality and coronary artery disease (Chapter 51), stroke (Chapter 413), high blood pressure (Chapter 67), adverse lipid profile (Chapter 213), type 2 diabetes mellitus (Chapter 237), metabolic syndrome, osteoporosis (Chapter 251), colon cancer (Chapter 199), breast cancer (Chapter 204), and obesity (Chapter 227). Physical activity also reduces the risk for falls, cognitive impairment in older adults, age-related muscle loss, and depression (Chapters 24 and 404). There is moderate evidence that physical activity reduces the risk of hip fracture, lung cancer, endometrial cancer, and sleep disorders. Some evidence suggests that physical activity reduces the risk for anxiety disorders, osteoarthritis, and back pain. Observational studies consistently report that physical activity delays age-related functional limitations and loss of independence.

The benefits of physical activity are independent of other risk factors. For example, a sedentary obese smoker achieves health benefits from exercise, even if smoking and obesity persist.

Epidemiologic studies report that low levels of activity are associated with an increased risk for adverse health outcomes, including up to a 52% increase in overall mortality, a doubling of mortality from cardiovascular disease, and a 29% increase in mortality from cancer. When a healthy diet, regular activity, and abstinence from smoking are considered simultaneously, the effect of lifestyle is dramatic. For example, one study attributed 82% of coronary events in women to the lack of adherence to a healthy lifestyle.

The main determinant of the health benefits of physical activity is volume. Substantial health benefits begin to occur with a volume of 500 to 1000 MET-minutes/week. An adult can accumulate 500 MET-minutes by walking at 3.0 miles per hour (a 3.3-MET activity) on 5 days a week for 30 minutes (3.3 METs × 5 × 30 minutes = ≈500 MET-minutes). When measured by caloric expenditure, this volume of walking in a 75-kg (165-lb) adult expends an extra 430 kcal above the 190 kcal that would have been expended under resting conditions.

The dose-response relationship between volume and health benefits appears to be curvilinear, such that the marginal benefit of activity at lower

TABLE 15-1 EXAMPLES OF MODERATE-INTENSITY AND VIGOROUS-INTENSITY ACTIVITIES

MODERATE INTENSITY
Walking briskly (3 miles per hour or faster, but not race-walking)
Water aerobics
Bicycling slower than 10 miles per hour
Tennis (doubles)
Ballroom dancing
General gardening
VIGOROUS INTENSITY
Race-walking, jogging, or running
Swimming laps
Tennis (singles)
Bicycling 10 miles per hour or faster
Jumping rope
Heavy gardening (continuous digging or hoeing, with heart rate increases)
Hiking uphill or with a heavy backpack

From U.S. Department of Health and Human Services. *2008 Physical Activity Guidelines for Americans.* http://www.health.gov/paguidelines.

TABLE 15-2 RELATIVE RISK OF CARDIOVASCULAR DISEASE IN THE WOMEN'S HEALTH INITIATIVE OBSERVATIONAL STUDY ($N = 73,743$)

MEDIAN MET-MINUTES/WK	MULTIVARIATE ADJUSTED RELATIVE RISK OF CARDIOVASCULAR DISEASE
0	1.0
252	0.89
600	0.81
1050	0.78
1968	0.72

Data from Manson JE, Greenland P, LaCroix AZ, et al. Walking compared with vigorous exercise for the prevention of cardiovascular events in women. *N Engl J Med.* 2002;347:716-725.

levels is large, and the benefit decreases with higher activity levels. Data from the Women's Health Initiative Observational Study (Table 15-2) provide an example of the dose-response effect. Compared with the least active women, the risk for cardiovascular disease was 19% less in women who averaged 600 MET-minutes/week, yet just 28% less in women who averaged 1968 MET-minutes/week. Dose-response effects are also found in intervention studies. For example, a randomized trial of two doses of exercise (doses equivalent to jogging 12 and 20 miles/week) found that the lower volume of exercise significantly improved plasma lipoproteins, but the higher volume had greater beneficial effects.[1]

TREATMENT

Therapeutic Health Benefits in Adults

Clinical practice guidelines assign a substantial therapeutic role to physical activity in patients with coronary heart disease (Chapter 51), high blood pressure (Chapter 67), type 2 diabetes (Chapter 237), obesity (Chapter 227), osteoporosis (Chapter 251), osteoarthritis (Chapter 270), claudication (Chapter 79), and chronic obstructive pulmonary disease (Chapter 88). Physical activity also plays a role in the management of depression and anxiety disorders, elevated cholesterol levels, pain, heart failure, syncope, stroke, back pain, dementia, and constipation and in the prophylaxis of venous thromboembolism.

Physical activity effectively opposes age-related loss of fitness and functional limitations. Randomized controlled trials demonstrate that exercise by sedentary older adults improves health-related physical fitness (e.g., aerobic exercise improves aerobic capacity) and has beneficial effects on functional limitations, such as a slow gait speed.[2] Generally, the benefits are most demonstrable in older adults with clinically significant functional limitations. Physical activity, especially balance training, prevents falls in older adults at increased risk for falling, such as those with impaired gait and balance.[3] It is probable that physical activity improves the ability to live independently, but evidence from randomized trials is incomplete.

Health Risks of Physical Activity

Physical activity and exercise have risks. Musculoskeletal injuries are by far the most common type of activity-related adverse event. The risk of injury depends on the type and volume of activity. Collision and contact sports have a much higher injury risk than noncontact activities such as walking, which is associated with about one musculoskeletal injury for every 1000 hours of walking for exercise. The weekly volume of activity is directly related to the risk of musculoskeletal injuries, but when following public health guidelines, which involves participating in about 500 to 1000 MET-minutes/week, the risk of injury is low. The risk of injury is directly related to the rate of increase in the dose of activity, with more rapid increases having higher risk. Previous musculoskeletal injuries and low fitness also increase the injury risk.

Overall, regular physical activity decreases the risk for sudden cardiac death and myocardial infarction; active adults have roughly a 70% lower risk of sudden death. However, relatively vigorous physical activity acutely increases the risk for these events in both active and inactive adults. About 5 to 10% of myocardial infarctions are associated with vigorous activity. Yet sudden death is a rare event during exercise, with published rates in the range of one death per year in 18,000 ostensibly healthy men and one death per 2.6 million workouts in fitness facilities.

Physical Activity Guidelines for Adults

For the first time, the U.S. Department of Health and Human Services has issued national physical activity guidelines: the *2008 Physical Activity Guidelines for Americans* (Table 15-3).

Recommended Amounts of Aerobic Activity for Prevention

To obtain substantial health benefits from physical activity, adults should do at least 150 minutes/week of moderate-intensity aerobic activity or 75 minutes/week of vigorous-intensity activity. Light-intensity activity is less than 3.0 METs, moderate-intensity activity is in the range of 3.0 to 5.9 METs, and vigorous-intensity activity is 6.0 METs or higher. There is insufficient evidence to determine whether the health benefits of 30 minutes of activity on 5 days a week differ from the health benefits of 50 minutes of activity on 3 days a week. Adults can also do an equivalent combination of both moderate- and vigorous-intensity activity, using the rule of thumb that one vigorous-intensity minute of activity counts the same as two moderate-intensity minutes.

TABLE 15-3 KEY PHYSICAL ACTIVITY GUIDELINES FOR ADULTS

- All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits.
- For substantial health benefits, adults should do at least 150 min (2.5 hr)/wk of moderate-intensity aerobic activity or 75 min (1.25 hr)/wk of vigorous-intensity aerobic activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity.
- Aerobic activity should be performed in episodes lasting at least 10 min and should be spread throughout the week.
- For additional and more extensive health benefits, adults should increase their aerobic physical activity to 300 min (5 hr)/wk of moderate-intensity or 150 min (2.5 hr)/wk of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity activity. Additional health benefits are gained by engaging in physical activity beyond this amount.
- Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on 2 or more days/wk, as these activities provide additional health benefits.

From U.S. Department of Health and Human Services. *2008 Physical Activity Guidelines for Americans.* http://www.health.gov/paguidelines.

Recommended Amounts of Muscle-Strengthening Activity for Prevention

Adults should perform activities that strengthen the major muscle groups of the body at least 2 days each week. The major muscle groups are the legs, hips, back, chest, abdomen, shoulders, and arms.

Flexibility Activity

Flexibility activities are an acceptable part of a physical activity regimen, but there is insufficient evidence that flexibility activities have any health benefits, even for preventing injuries. Flexibility training does increase flexibility, and it may facilitate the types of physical activity that do have health benefits. If so, flexibility training is more important for people with reduced flexibility, such as older adults with age- and disease-related changes in range of motion.

Balance Activity

Balance training is currently recommended only for adults at increased risk for falls, such as those older than 65 years with impaired gait or balance or frequent falls. Examples of balance exercises include sideways walking, backward walking, heel walking, and standing using a narrow base of support. Tai chi programs include exercises that improve balance. The optimal frequency, duration, and type of balance training are unknown. Preferably, adults at risk for falls should do balance training at least 3 days/week and follow an evidence-based program demonstrated to reduce the risk of falls.

Inactivity versus Sitting Time

Inactive adults engage in no activity that counts toward meeting the national guidelines. Doing some physical activity is clearly preferable to inactivity. A separate issue is whether more time spent sitting has an adverse effect on health, independent of a person's volume of moderate- to vigorous-intensity activity. It appears likely that spending more time in light-intensity baseline activity and less time sitting has an independent beneficial effect on health. Certainly, light-intensity activities expend calories and can be recommended as part of a plan to achieve and maintain a healthy weight. However, data are currently insufficient to issue guidelines on the amounts and patterns of sitting time that cause adverse health effects in adults.

Guidelines for Weight Management

The amount of activity required to maintain a healthy body weight varies widely among adults (Chapter 227). For some adults, the physical activity levels recommended in the guidelines will result in a stable, healthy body weight. Many adults, however, need higher levels of activity to achieve a healthy weight. These individuals should restrict their caloric intake and gradually increase their physical activity each week, to the point that is effective in achieving and maintaining a healthy body weight for them.

Additional Guidelines for Older Adults

In addition to balance training, the 2008 guidelines contain other recommendations specifically for older adults. Older adults who cannot do 150

minutes/week of moderate-intensity activity should be as active as their abilities and conditions allow. Progressive resistance strength training improves physical function in the elderly.[4] Older adults should determine their level of physical activity using relative intensity, not absolute intensity. This latter guideline seeks to avoid inappropriately high levels of effort in older adults with low fitness.

Recommending Physical Activity in Clinical Settings

Promoting physical activity in clinical settings involves essentially the same steps as the five As of smoking cessation: ask, advise, assess, assist, arrange. (1) Ask about the amount of physical activity a patient typically engages in each week by questionnaire or interview. (2) Advise all patients to participate in at least a moderate amount of physical activity each week. Advise patients who do not meet the recommendations to increase their physical activity gradually to a specified minimal level, and tailor the recommendations according to their medical conditions. (3) Assess the next step or steps a patient needs to take to become more active. (4) Assist the patient in taking these steps. (5) Arrange an appointment to follow up on efforts to increase activity.

Health care providers should ask and advise patients about physical activity regularly. One quality-of-care measure assesses whether asking and advising are done at least once a year in older adults. Some recommend that physical activity should be a "vital sign" that is assessed at every visit. Studies consistently report that adults (especially older adults) identify their health care providers as an important source of advice on physical activity.

The U.S. Preventive Services Task Force last reviewed the effectiveness of primary care–based counseling (i.e., assessing and assisting) in 2002. Counseling protocols vary among research studies; some have been effective, and some not. Overall, the task force concluded that the evidence was insufficient to recommend for or against counseling. In relatively healthy patients, a reasonable approach is to counsel selected patients who request information about physical activity, using a protocol that has been evaluated and shown to be effective. For example, a randomized trial demonstrated that an exercise prescription program increased physical activity and quality of life in women aged 40 to 76 over a 2-year period, although falls and injuries also increased.[5]

Exercise Prescription

For patients who want to exercise, a clinician can provide an exercise prescription. The prescription includes (1) the type, frequency, duration, and intensity of aerobic exercise; (2) the exercise movements (e.g., bench press), repetitions, and sets for resistance exercise; (3) other exercises such as stretching, balance exercises, warm-up, and cool-down; and (4) risk management strategies, such as increasing levels of activity gradually over time.

A prescription for vigorous-intensity aerobic exercise generally specifies a minimum frequency of at least 3 days/week, a minimum duration of 20 minutes, and an intensity of 70 to 85% of the maximal heart rate (HR_{max}). A prescription for moderate-intensity exercise would specify an intensity of 40 to 60% of oxygen uptake reserve (or 50 to 69% of HR_{max}) 3 or more days/week to reach an adequate volume. Training at the upper limits of vigorous intensity (85 to 89% of HR_{max}) is discouraged because of concern about injury and adherence. (Higher exercise intensities are commonly regarded as less pleasant.)

A prescription for resistance training generally specifies 8 to 10 separate exercises that train the major muscle groups, with at least one set of 8 to 12 repetitions of each exercise on 2 or 3 days/week. Some recommend that older adults do 10 to 15 repetitions in a set.

Lifestyle Prescription

A *lifestyle prescription* refers to approaches that integrate physical activity into daily life. For example, rather than walking specifically for exercise, a person walks to work or walks for pleasure as a recreational activity. Common ways to integrate physical activity into daily life are walking and biking for transportation and performing yard work and gardening.

Tailoring the Recommendation

Recommendations need to be tailored to individual abilities, individual preferences, medical conditions, and behavior techniques that improve adherence. Randomized trials show that home-based programs are superior to center-based programs in terms of long-term adherence.[6] Although center-based programs are preferred by some, in most cases they serve a short-term purpose, such as assisting adults to initiate regular exercise.

A target level of physical activity below that of preventive recommendations is appropriate for adults with very low fitness, a large burden of chronic disease (e.g., severe chronic obstructive lung disease), or major functional limitations. An assessment of the nature of the activity limitation and the individual's capabilities and preferences can determine the target activity level and other details of the activity recommendation. Often, promoting physical activity in such adults relies on health care and community resources designed for people with preexisting limitations, such as cardiac rehabilitation, pulmonary rehabilitation, and exercise classes for adults with arthritis.

Risk Management

Strategies to reduce injury include increasing physical activity gradually over time, selecting activities in which collision or contact with people or objects is unusual, increasing physical fitness, using appropriate gear and sports equipment (e.g., bike helmets), engaging in activities in safe environments, and following basic safety rules and policies. Popular activities such as walking, biking, swimming, and gardening have a low risk of injury. When increasing the level of physical activity, the guidelines recommend using relative intensity to determine the level of effort, starting with relatively moderate-intensity activity, then increasing the duration and frequency first and the intensity last. In general, adding 5 to 15 minutes of moderate-intensity activity per session, two to three times a week, to a person's usual activities carries a low risk of musculoskeletal injury and no known risk of sudden cardiac death.

There is no evidence of the protective value of a medical consultation in healthy people of any age who seek to increase their level of physical activity. The U.S. Preventive Services Task Force recommended against routine screening for coronary disease in adults at low risk for it and concluded that in adults at high risk for coronary disease, there is insufficient evidence to recommend for or against screening with resting electrocardiography, exercise treadmill test, or electron-beam computed tomography.

Coordination between Medical Care and Community

Many factors affecting physical activity levels are difficult to influence in medical care settings, such as the characteristics of the communal environment (e.g., parks and recreational facilities) and the social environment (e.g., crime and social support). Community-level interventions that address such characteristics are essential to promoting physical activity. Effective community-based interventions include school physical education, social support interventions, community-wide campaigns, enhancement of access to places where physical activity is possible, and interventions that involve community design, such as improving the connectivity of streets and the walkability of neighborhoods. Medical care and community efforts should be synergistic and mutually supportive. For example, health plans should be advocates for evidence-based community interventions. Community programs should serve as resources for evidence-based therapeutic activity for selected chronically ill adults, such as exercise classes designed to reduce the risk of falls.

ADOLESCENT MEDICINE

DEBRA K. KATZMAN AND LAWRENCE S. NEINSTEIN

Adolescence, a period of transition between childhood and adulthood, is marked by critical biological, psychological, social, and cognitive changes. During this unique developmental period, patterns of behaviors and lifestyle choices are established that can influence current and future health, and unique medical and psychological problems can emerge. Adult-oriented health care providers play a pivotal role in engaging youth in their health and in providing health care to adolescents and young adults.

NORMAL PHYSICAL GROWTH AND DEVELOPMENT

Biologic growth and development in adolescents are signified by the onset of puberty (Chapter 243), which varies temporally among adolescents and explains why adolescents of the same chronologic age can vary greatly in physical appearance. Usually the first visible sign of puberty among females is thelarche, or the development of breast buds, which occurs on average at 10.5 years in white girls and 1 year earlier in African-American girls (Chapter 243).

Menarche occurs 2 to 4 years after the initial appearance of breast buds and pubic hair. The average age of menarche is 12.9 years for white girls and 12.2 years for African-American girls. Menstrual periods are not always regular during the first 2 years after menarche. At menarche, only 20% of cycles are ovulatory; it may take up to 4 years for 80% of cycles to be ovulatory. The average length for the completion of puberty in females is 4 years (range, 1.5 to 8.0 years).

Puberty begins about 2 years later in boys than in girls. The first physical sign of puberty in boys, testicular enlargement and thinning of the scrotum, occurs at 11.5 years. Adrenarche occurs 6 months later at an average age of 12.0 to 12.5 years (Chapter 242). Facial hair starts to grow about 3 years after pubic hair. The completion of puberty in males can take an average of 3 years (range, 2 to 5 years).

Pubertal weight gain accounts for about half of a person's ideal adult body weight. Peak weight gain follows the linear growth spurt by 3 to 6 months in adolescent girls and by about 3 months in adolescent boys. The average weight gain during puberty among adolescent females is 15 to 55 lb, or 7 to 25 kg (mean gain, 38.5 lb, or 17.5 kg). Overall, adolescent males gain 15 to 65 lb, or 7 to 30 kg, during puberty (mean gain, 52.2 lb or 23.7 kg).

Boys' body fat levels decrease during adolescence, dropping to 12% body fat by the end of puberty. On average, adolescent girls' lean body mass falls from 80 to 75%, whereas their average body fat levels increase from 16 to 27% by the end of adolescence. By the time adolescent girls are 16 years of age and adolescent boys are 18 years of age, they have accrued more than 90% of their adult skeletal mass. *Sexual maturity ratings* (SMRs), also known as Tanner staging, are used to describe the progression of secondary sexual characteristics that occur in adolescents, irrespective of chronologic age. SMR is based on the development of breasts and the appearance of pubic hair among girls (Fig. 16-1) and on testicular and penile development and the appearance of pubic hair among boys (Fig. 16-2). SMR 1 corresponds to the prepubertal stage; puberty has not begun, and no sexual development has occurred. SMR 2 to SMR 5 indicate the progression of puberty to adulthood. Once young people reach SMR 5, they have fully developed secondary sexual characteristics. Sexual maturation correlates with linear growth, changes in weight and body composition, and hormonal changes. Sexual maturation provides important assurance of the normal progression of puberty or identification of abnormal pubertal development.

NORMAL PSYCHOSOCIAL DEVELOPMENT

Adolescence is often divided into three psychosocial developmental phases: early adolescence (11 to 13 years), middle adolescence (14 to 16 years), and late adolescence (17 to 21 years). In early adolescence, adolescents begin to separate from their parents and establish an individual identity. As adolescents pull away from their parents in search of their own identity, their peer group takes on an important and special significance.

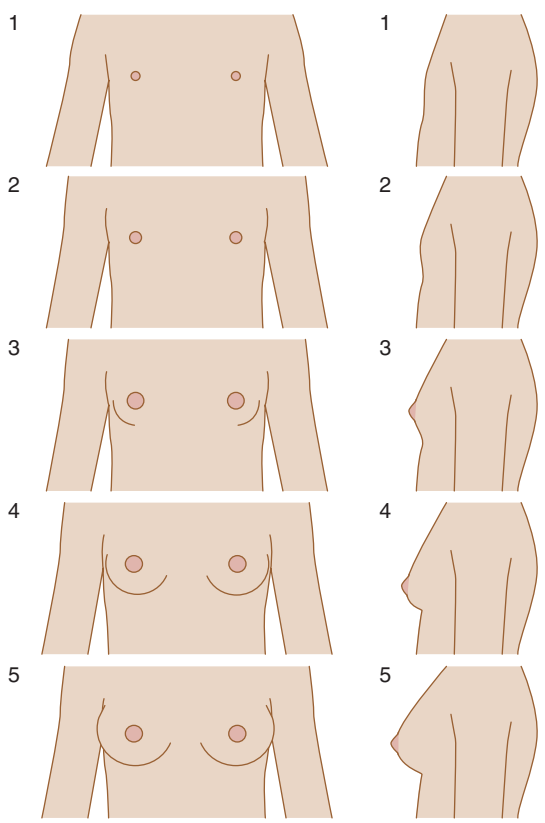

FIGURE 16-1. Female breast development. *Sexual maturity rating 1 (SMR 1)*: Preadolescent; no glandular tissue. Areola and papilla: Areola conforms to general chest line. *SMR 2:* Breast buds appear; areola is slightly widened and projects as small mound. *SMR 3:* Enlargement of the entire breast with protrusion of the papilla or of the nipple. Breast and areola enlarge with no separation of their contours. *SMR 4:* Enlargement of the breast and projection of areola and papilla as a secondary mound. *SMR 5:* Adult configuration of the breast with protrusion of the nipple; areola no longer projects separately from remainder of breast. (Redrawn from Daniel WA, Paulshock BZ. A physician's guide to sexual maturity rating. *Patient Care*. 1979;30:122. Original illustration by Paul Singh-Roy.)

At the beginning of adolescence, cognitive abilities are dominated by concrete thinking. Young adolescents lack abstract reasoning capabilities, problem-solving skills needed to overcome barriers to behavioral changes, and the ability to appreciate how their current behaviors can affect their future health status.

Middle adolescence is characterized by growth in emotional autonomy and increasing separation from family. The adolescents' peer groups play a powerful role, and adolescents are increasingly involved in partnering relationships that include dating, sexual experimentation, and adverse health behaviors such as smoking cigarettes, drinking alcohol, using street drugs, and being truant. Abstract reasoning skills emerge but often regress to concrete thinking when adolescents are faced with stressful situations. These adolescents begin to understand the relationship between health behaviors and future health status, but peer pressure makes it challenging to make health-related choices.

During late adolescence, young people become increasingly more economically and emotionally independent. Peer group values become less important, and young people spend more time in a relationship with one person. The late stage of adolescence is characterized by the development of a strong personal identity. Abstract reasoning skills expand, and older adolescents have problem-solving skills that help them overcome challenges to behavioral change.

VITAL STATISTICS

Although adolescents are generally perceived to be healthy, adolescent morbidity and mortality are the result of risky behaviors and social forces (Table 16-1). Adolescents increasingly engage in risky behaviors with each year of adolescence, especially between the ages of 11 and 16. Unintentional injury, homicide, and suicide are the leading causes of death in 15- to 24-year-olds and account for 71% of all adolescent and young adult deaths. About 75% of these causes of death and injury are preventable.

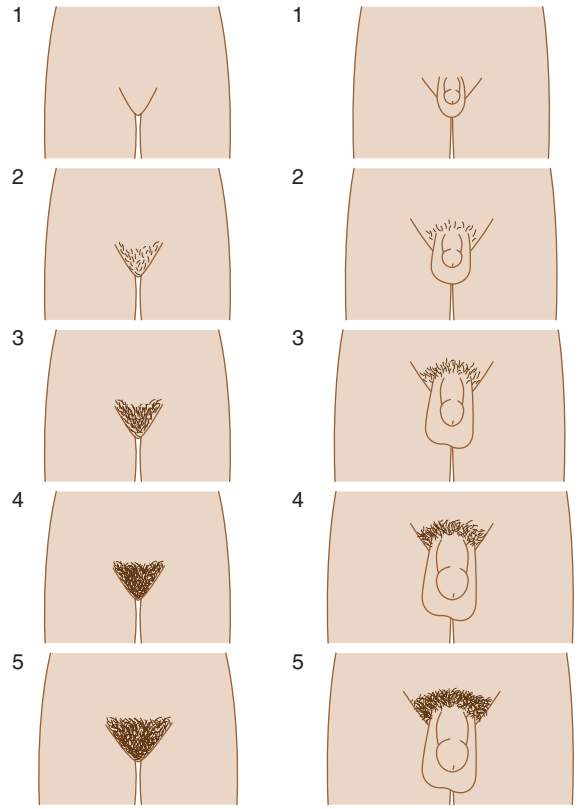

FIGURE 16-2. Male genital development. *SMR 1:* Penis preadolescent. Testicular volume <4 mL. *SMR 2:* Penis slight or no enlargement. Beginning enlargement of testes; testicular volume 4 to 8 mL; scrotal skin reddened, thinner. *SMR 3:* Penis increased in length. Testicular volume 10 to 15 mL. Further enlargement of scrotum. *SMR 4:* Penis larger in breadth, glans penis develops. Testes and scrotum nearly adult; testicular volume 12-20 mL. *SMR 5:* Penis adult size; testicular volume greater than 25 mL. **Female and male pubic hair development.** *Sexual maturity rating 1 (SMR 1):* Prepubertal; no pubic hair. *SMR 2:* Small amount of scanty, long, slightly pigmented, along the base of the scrotum and phallus in the male and the medial border of the labia majora in females. *SMR 3:* Darker, coarser, starts to curl, small amount, extending laterally. *SMR 4:* Coarse, curly; resembles adult type but does not extend to the medial surface of the thighs. *SMR 5:* Abundant, adult-type pattern; hair extends onto the medial aspect of the thighs. (Redrawn from Daniel WA, Palshock BZ. A physician's guide to sexual maturity rating. *Patient Care*. 1979;30:122. Original illustration by Paul Singh-Roy.)

TABLE 16-1 LEADING CAUSES OF DEATH IN U.S. ADOLESCENTS

CAUSE	PERCENTAGE OF DEATHS IN YOUTH AGED 15-24 YEARS
Unintentional injury	47
Homicide	16
Suicide	12
Malignancy	5
Heart disease	3
Congenital anomalies	1.3
Cerebrovascular disease	0.6
Human immunodeficiency virus	0.6
Influenza and pneumonia	0.5
Complicated pregnancy	0.5
All others	14

From U.S. Census Bureau, *2008 National Population Projections*, released August 2008.

Unintentional and Intentional Injuries

Unintentional injuries account for 44% of all injury deaths to children and adolescents. For every childhood death caused by injury, another 34 hospitalizations and 1000 emergency department visits occur. The major causes of unintentional injuries to adolescents are motor vehicle crashes, being struck by or against an object or person, cuts from sharp objects, and falls. Factors that contribute to adolescent injuries include socioeconomic factors (poor children are at greatest risk for injury), environmental factors (hazards such as all-terrain vehicles, backyard swimming pools, firearms, kerosene heaters, and gang activity), school environment, and developmental factors.

About 20% of all adolescents, especially adolescent girls in heterosexual relationships, report having experienced either psychological or physical violence from a dating partner. About 20 to 30% of students in grades 6 to 10 are involved in bullying, as a bully, victim, or bully-victim (those who are both aggressive to peers and victimized by peers). For younger adolescents, bullying can lead to a significantly higher risk of psychosomatic problems.

Homicide is the second leading cause of death in the 15- to 24-year-old population and the number one cause of death among African-American males 15 to 24 years of age. About 75% of homicides in older adolescents and young adults involve firearms.

Suicide (Chapter 404) is the third leading cause of death among adolescents and young adults 10 to 24 years of age. Native Americans and white youth 15 to 24 years of age have the highest suicides rates, whereas African-American youth 15 to 19 years of age and Asian youth 20 to 24 years of age have the lowest. The estimated ratio of attempted-to-completed suicides among adolescents ranges between 50:1 and 100:1. The most common methods used in suicide attempts are drugs or alcohol, whereas suffocation, hanging, or use of firearms is associated with completed suicides. Death rates caused by firearms are eight times higher in adolescent boys than in adolescent girls.

Prevention of Injuries

Clinicians should discuss the impact of alcohol and drugs on driving and stress the importance of routine use of seat belts when driving in a motor vehicle. Clinicians also should discuss safety during sports activities, such as use of bicycle helmets and sports-related protective gear.

Other Diseases

Excluding intentional and unintentional injuries, cancer is the leading cause of death in adolescents and is the leading cause of death by disease. Cancers with an increased incidence in adolescents include Hodgkin's disease (Chapter 192), germ cell tumors (Chapter 206), central nervous system tumors (Chapter 195), non-Hodgkin's lymphoma (Chapter 191), thyroid cancer (Chapter 233), malignant melanoma (Chapter 210), and acute lymphoblastic leukemia (Chapter 189). Human immunodeficiency virus (HIV) continues to be one of the ten leading causes of death among people 15 to 24 years of age.

APPROACH TO THE ADOLESCENT PATIENT

When interviewing adolescent patients, the clinician should consider the adolescents' physical, cognitive, and psychosocial developmental stage, their growing autonomy and increasing role in taking responsibility for their own health and well-being, and their individual progression from childhood to adulthood. Chronologic age is not a guarantee that all adolescents will be at the same stage of physical, cognitive, and psychosocial development. The clinician should offer adolescent health care in a sensitive, flexible, and developmentally and culturally appropriate manner.

The clinician can meet with the adolescent alone at first to give the adolescent the message that she or he is the patient and the clinician is most eager to hear what the adolescent has to say. Conversely, the clinician can meet with the adolescent and her or his parents or guardians together for the initial part of the interview and then meet with the adolescent alone; this approach permits the clinician to develop an understanding of the reason for the visit from the perspective of the adolescent and his or her parents or guardians, and to communicate that input from both the adolescent and the parents or guardians is highly valued. This approach also provides an opportunity for the clinician to observe the interaction between the adolescent and parents or guardians. The final approach to the interview is to greet the adolescent and family, and request a meeting with the parents or guardians alone. This approach allows the parents or guardians to discuss concerns about the adolescent that they may not feel comfortable raising in the presence of the adolescent. Having this information may improve the focus of the visit. Using this approach, the encounter with the parents or guardians is then followed by the clinician meeting with the adolescent alone. With this interview structure, it is important that the adolescent be present from the time he or she meets with the clinician until the end of the visit, so that the adolescent does not perceive a breach of confidentiality.

Confidentiality

Issues of consent and confidentiality are central in the physician-adolescent interaction. Adolescents appreciate clinicians whom they trust and who can assure them of confidentiality. When guaranteed confidentiality, adolescents are more likely to seek necessary medical care, disclose sensitive information, and trust their clinician. Under these circumstances, most adolescents will involve their parents in their care. Parents appreciate education about the concept of confidentiality and recognize the importance of allowing the adolescent the opportunity to speak alone with their clinician. Confidentiality is also important for clinicians. To make an accurate diagnosis and provide treatment, the clinician must obtain all relevant information from the adolescent. If the adolescent fears that such information will not be kept confidential, she or he may not provide all the necessary factual information.

Confidentiality and defining the limits of confidentiality should be discussed with the adolescent and his or her parents or guardians at the beginning of the interview. The adolescent and family need to know that the clinician will intervene if he or she believes that the adolescent's actions may cause him or her, or another person, significant harm. Examples of situations in which the clinician would not maintain confidentiality when dealing with young people include disclosure of past or current sexual abuse, current suicidal intent, and disclosure of homicidal intent.

Those who work with young people must have a clear understanding of consent and confidentiality and should make sure that adolescents are aware of confidentiality policies and practices. The duty of confidentiality does not preclude encouraging and empowering adolescents to talk to their parents or guardians about important health care issues and include them in discussions of these issues. The legal definition of confidentiality varies, depending on geographic location. It is the clinician's responsibility to familiarize himself or herself with the legal issues of confidentiality (as they relate to the adolescent patient and his or her parents or guardians) in their locality.

Another goal of the interview is to build rapport with the adolescent and his or her parents or guardians. Clinicians can establish rapport with the adolescent at the start of the interview by creating an environment that is nonjudgmental, unintimidating, and supportive. The clinician's genuine interest in the adolescent is paramount. It is helpful to encourage the adolescent to talk about himself or herself—friends, hobbies, school. The clinician should listen carefully to the adolescent's statements and feelings. Sensitivity to and understanding of the adolescent's developmental stage and cultural background are important when interviewing an adolescent and interpreting answers accurately. The clinician should be respectful of the adolescent's growing need to be independent and desire to be treated as an individual person. Taking the time to build rapport is key to engaging the adolescent in a discussion of his or her personal health concerns with the clinician.

Preventive Health Care

Preventive health care for adolescents (Chapters 14 and 17) should promote physical and mental health and healthy physical, psychological, and social growth and development. Positive behaviors such as exercise (Chapter 15) and nutritious eating (Chapter 220) should be encouraged, and health risk behaviors such as unsafe driving, use of tobacco (Chapter 31), unsafe sexual behaviors, and excess alcohol (Chapter 32) should be discouraged. Because lifelong health habits are established during adolescence, it is an important time to invest in health promotion and preventive services.

Components of the Adolescent Care Health Visit

History

Open-ended, nonjudgmental, developmentally appropriate, and gender-neutral questions help put the adolescent at ease and produce informative answers (Chapter 14). In addition to a standard medical history, the assessment should include a psychosocial history from the adolescent, either through a screening questionnaire or during the interview with the adolescent alone. The HEEADSSS assessment, which is a valuable tool for obtaining a comprehensive psychosocial history, covers the following topics:

- **Home:** Family members, living arrangements, and relationships
- **Education/Employment:** Academic or vocational success and future plans
- **Eating:** Concerns about weight or body image or disordered eating attitudes and behaviors
- **Activities**: Recreational activities, dating, and relationships
- **Drugs:** Use of tobacco, alcohol, illicit drugs, anabolic steroids, and driving while intoxicated
- **Sexuality:** Sexual orientation, sexual activity, and sexual abuse
- **Suicide** (mental health): Feelings of sadness, loneliness, depression, or suicidal thoughts
- **Safety:** Risk of unintentional injury or violence, fighting, or weapon carrying

Physical Examination

In general, the adolescent physical examination should occur without a parent or guardian present. In some situations, the adolescent is asked whether he or she would prefer to have a parent in the room during the physical examination. A male clinician should request that a female health care provider be present during the physical examination of a female patient, especially during the breast and genital examination. In theory, a female clinician should request a male health care provider be present during the genital examination of a male patient.

Care should be taken to ensure the adolescent's privacy. Providing an examination gown that covers the trunk and genital area is important. Talking with the adolescent during the examination also tends to increase comfort; explaining the procedures and commenting on the results are helpful. A comprehensive physical examination (Chapter 14) should include measuring the adolescent's weight and height, calculating his or her body mass index, plotting these measurements on standardized growth charts, and determining the adolescent's SMR.

Young women who have HIV or who are immunosuppressed (e.g., those having chemotherapy, transplantation) should have a baseline Papanicolaou smear 3 years after their first sexual intercourse. Other indications for a pelvic examination in an adolescent include symptoms of vaginal or uterine infection, menstrual irregularities (e.g., amenorrhea, dysfunctional uterine bleeding, menorrhagia, and severe dysmenorrhea), undiagnosed abdominal and pelvic pain, tenderness, mass, trauma, sexual abuse, or assault. A careful sexual history, a review of symptoms, and urine or patient-obtained specimens may be an alternative to the pelvic examination.

Conclusion of the Health Visit

At the conclusion of the adolescent health visit, the clinician should review the findings with the adolescent and talk about what happens next. This discussion should not be rushed; the adolescent should have the opportunity to ask questions, get clarification, make comments, and respond to suggestions. The clinician should discuss with the adolescent what information will remain confidential. The clinician should then meet with the adolescent and the parents or guardians (if they have accompanied the adolescent to the health visit) to review the outcomes and discuss the nonconfidential issues.

Immunizations

Adolescents should be brought up-to-date on all recommended immunizations (Chapter 17).

REPRODUCTIVE HEALTH

Reproductive health care includes issues of adolescent sexual development, adolescent sexual behaviors, adolescent pregnancy, and contraception. In the United States, nearly 50% of high school boys and girls in grades 9 to 12 have had vaginal intercourse (50% of males, 46% of females) at least once. This number increases from 27% of females and 38% of males in grade 9 to about 65% of both boys and girls by their senior year. In addition, 4% of females and 10% of males in grades 9 to 12 started having sex before they were 13 years old, 14% of adolescents have had four or more sex partners during their lives, and 38% of sexually active high school students did not used a condom when they last had sexual intercourse. About 60% of adolescent girls who are 13 years of age or younger when they first had sexual intercourse report having involuntary intercourse. Adolescents are more likely to report engaging in oral than vaginal sex because they perceive oral sex as significantly less risky (fewer health, social, and emotional consequences) than vaginal sex, but adolescents who engage in oral sex also are more likely to engage in vaginal sex.

Every year about 800,000 pregnancies occur in females 15 to 19 years of age in the United States. About 50% of these pregnancies result in a live birth, about 35% end with an abortion, and about 15% end with a miscarriage or stillbirth. The birth rate for mothers 15 to 27 years of age decreased from 38.6 in 1991 to 22.1 in 2004 because of increased use of effective

contraception and decreased sexual activity. Adolescent pregnancy is more common among black and Hispanic females as well as females from low-income families.

Positive outcomes of adolescent pregnancies are enhanced with good prenatal care, adequate initial and follow-up prenatal visits, nutritional counseling, assessment of psychosocial issues, and substance abuse counseling. Adolescents younger than 15 years are at increased risk for premature and low-birthweight infants; those older than 15 years who have adequate prenatal care do not have increased adverse outcomes.

Contraception

The most commonly used contraceptive methods in adolescents are oral contraceptive pills (OCPs) and condoms, although new hormonal delivery systems such as transdermal patches, vaginal rings, and implants are convenient and effective (Chapter 246).

Sexually Transmitted Diseases

Every year, about 4 million adolescents in the United States acquire a sexually transmitted disease (Chapter 293), representing 25% of the total cases of sexually transmitted disease diagnosed annually. *Chlamydia trachomatis,* which is the most commonly reported bacterial sexually transmitted disease, is reported annually in about 2.8% of female adolescents 15 to 19 years of age and 0.5% of male adolescents of the same age. The annual incidence of gonorrhea is about 0.6% for female adolescents 15 to 19 years of age and 0.4% for adolescent males of the same age. In adolescents, HIV (Chapter 395) is contracted primarily as a sexually transmitted disease, and adolescents and young adults 15 to 24 years of age represent 14% of all new HIV diagnoses in the United States. Human papillomavirus (Chapter 381), which is the most prevalent of all sexually transmitted diseases in 15- to 24-year-olds, has a prevalence of about 20% in adolescent girls 14 to 17 years of age.

Adolescents are at greater risk of acquiring sexually transmitted diseases because they are more likely to engage in unprotected sexual intercourse with concurrent partners who have multiple other partners. Adolescent girls may have persistent vaginal columnar epithelium that is more susceptible than squamous epithelium to *Neisseria gonorrhea, C. trachomatis,* and HPV, as well lower levels of immunoglobulin A in their cervical mucus. Treatment may be delayed owing to an inability to access confidential health care services, lack of health care coverage, poverty, and drug trafficking and use.

Chlamydial infections (Chapter 326), often asymptomatic or minimally symptomatic in women, usually present with a vaginal discharge in young adolescent girls. Otherwise, clinical presentations and treatments of sexually transmitted diseases (Chapter 293) in adolescents are similar to those in adults.

About 20% of adolescents given prescriptions for a sexually transmitted disease treatment fail to fill their prescriptions. Therefore, whenever available, an observed single-dose therapy is recommended. In addition, expedited partner therapy (EPT), which is the treatment of sexual partners without requiring a prior clinical evaluation or prevention counseling, reduces the level of recurrent sexually transmitted diseases better than does standard management. Clinicians should consider the use of EPT for partners exposed within 60 days to heterosexual males and females with chlamydia or gonorrhea infections when in-person evaluation and treatment are unlikely.

ADOLESCENT EATING DISORDERS

Eating disorders (Chapter 226) commonly begin during adolescence. For adolescent-onset anorexia nervosa, bulimia nervosa, and other eating disorders, early recognition and aggressive treatment are critical to a successful outcome. The medical complications of eating disorders in adolescents include growth retardation, pubertal delay, low bone mineral density, and changes in brain structure and cognitive function. These complications, which occur early in the disease process, may not be completely reversible, thereby underscoring the need for early and aggressive treatment.

The goal of treatment is to restore physical health, normal eating-behavior patterns, and mental health and to reduce the impact of the eating disorder on the quality of life. Successful management strategies for adolescents with eating disorders include early restoration of a normal nutritional and physiologic state, involvement of the family in the treatment, and incorporation of an interdisciplinary team in the treatment. Adolescents should be treated at a facility where the health professionals understand eating disorders and have experience treating adolescents.

SUBSTANCE ABUSE

Nearly half of adolescents try an illicit drug (Chapter 33) by the time they finish high school. About 75% of adolescents consume alcohol (Chapter 32) by the end of high school, and about half report having been drunk at least once in their life. Adolescents who begin using alcohol or drugs before 15 years of age are more than five times more likely to develop an addictive disorder later in life, compared with those who first use alcohol at 21 years of age. About 45% of adolescents use marijuana, and 20% of 12th graders are current smokers.

Adolescents start using drugs or alcohol primarily because of social pressures but report continuing them to feel good or cope with difficulties. Boys tend to initiate drug and alcohol use at younger ages than girls, but once girls begin to experiment, they are just as likely as boys to use drugs. Boys are more likely to consume marijuana, steroids, and smokeless tobacco, whereas girls are more likely to abuse amphetamines and methamphetamine.

Adolescents with poor self-esteem, low motivation, and poor academic achievement have a greater propensity for alcohol and drug abuse than those with positive self-esteem. Adolescents with a family member with a history of alcohol or other drug abuse are at greater risk. Adolescents are less likely to succumb to external pressures toward drug use if they have a strong sense of attachment to parents who clearly communicate their disapproval.

Signs and symptoms suggestive of substance abuse include changes in physical appearance, poor hygiene or dress, wearing long-sleeved shirts to hide scarring at injection sites, persistent cough or bronchitis, difficulty sleeping, sudden weight loss or weight gain, sudden changes in personality, aggressive behavior, irritability, nervousness, giddiness, changes in peer group, increased isolation from peers or family, depression, loss of interest in once favorite activities, decline in performance or attendance at school or work, forgetfulness, increased secretiveness, money or objects disappearing from the household, and prescription drugs that seem to be used up too quickly.

A validated screening tool for alcohol and substance abuse (Table 16-2) should be used in adolescents. Adolescents who answer "yes" to one of the six questions should receive advice on the adverse effects of substance abuse. Those who answer "yes" to two or more questions are at high risk and require further assessment or referral (Chapters 32 and 33). Urine drug testing has low sensitivity for detecting drug use, and there is no consensus about its role for screening adolescents.

Adolescent substance use can compromise psychological and social development, cause behavioral problems, and lead to a variety of high-risk behaviors. Alcohol and drug use contributes to more than 40% of adolescent deaths from motor vehicle crashes, to suicide attempts, and to an increased risk for subsequent use and its related problems in adulthood.

Historically, substance abuse treatment has been based on abstinence. More recently, a harm-reduction approach has gained acceptance. Adolescents discontinue drug and alcohol use mainly because of concern about their negative effects, and community-based interventions can be effective.■ To reduce alcohol abuse over time, individual interventions have a larger impact than family-based interventions.■

TABLE 16-2 CRAFFT SCREENING TOOL FOR DRUG AND ALCOHOL USE IN ADOLESCENTS

The adolescent is instructed, "Please answer these next questions honestly. Your answers will be kept confidential. During the past 12 months, did you …"
- Drink any alcohol (more than a few sips)?
- Smoke any marijuana or hashish?
- Use anything else to get high?

If the adolescent answers "No" to the three opening questions, the provider only needs to ask the adolescent the first question—the CAR question. If the adolescent answers "Yes" to any one or more of the three opening questions, the provider asks all six CRAFFT questions.
- **C**—Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs?
- **R**—Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in?
- **A**—Do you ever use alcohol/drugs while you are by yourself, ALONE?
- **F**—Do you ever FORGET things you did while using alcohol or drugs?
- **F**—Do your family or FRIENDS ever tell you that you should cut down on your drinking or drug use?
- **T**—Have you gotten into TROUBLE while you were using alcohol or drugs?

CRAFFT is a mnemonic acronym of first letters of key words in the six screening questions. The questions should be asked exactly as written.

CHRONIC ILLNESS AND TRANSITION

The prevalence of chronic diseases in adolescents has increased significantly because advances in medical technology and treatments have increased the survival of young people with childhood diseases formerly considered lethal. About 15% of adolescents in the United States live with a chronic illness. Chronic illness may affect the adolescent's development, or the adolescent's development may affect the illness. For example, cystic fibrosis (Chapter 89) may delay puberty and hinder normal peer development. Puberty can exacerbate diabetes mellitus (Chapter 236). Increased risk-taking by adolescents with diabetes, asthma, or chronic renal failure can hinder their compliance with their medication regimen.

Any chronic illness may limit age-appropriate activities and development. Adolescents with a chronic illness must have effective contraception and effective methods for preventing sexually transmitted diseases.

Adolescents in general, and those with special health care needs in particular, require a smooth, seamless, coordinated, and developmentally appropriate transition to the adult health care system. Barriers to a successful transition include a lack of adult physicians who can manage chronic childhood conditions (e.g., congenital heart disease; Chapter 69); patients, families, and pediatric subspecialists who are reluctant to terminate long-standing relationships; and patients and families who are poorly equipped to find their way in the adult health care system.

As adolescents move closer to the age of transfer, professionals should provide developmentally appropriate information and skills to support them and their families as they negotiate the adult health care system.

Adolescents benefit from an introductory visit with their adult-oriented care provider before leaving the pediatric health care system. This visit should give the adolescent a clearer idea about his or her new role as an adult patient, especially about expectations around decision making, giving consent, and the role of the family in his or her health care. The patient, family, and pediatric and adult health care systems should view the transition as a natural part of the developmental process of care for all adolescents.

IMMUNIZATION

WALTER A. ORENSTEIN AND WILLIAM L. ATKINSON

Immunization is one of the most cost-effective means of preventing morbidity and mortality from infectious diseases. Routine immunization, particularly of children, has resulted in decreases of 90% or more in reported cases of measles, mumps, rubella, congenital rubella syndrome, poliomyelitis, tetanus, invasive *Haemophilus influenzae* and diphtheria. In many circumstances, immunization not only prevents morbidity and mortality but also, in the long run, reduces health care costs.

GENERAL CHARACTERISTICS OF IMMUNIZATIONS

Immunization protects against disease or the sequelae of disease through the administration of an immunobiologic—vaccines, toxoids, immune globulin preparations, and antitoxins. Protection induced by immunization can be active or passive.

Active Immunization

Administration of a vaccine or toxoid causes the body to produce an immune response against the infectious agent or its toxins. Vaccines consist of suspensions of live (usually attenuated) or inactivated microorganisms or fractions thereof. Toxoids are modified bacterial toxins that retain immunogenic properties but lack toxicity. Active immunization generally results in long-term immunity, although the onset of protection may be delayed because it takes time for the body to respond. With live attenuated vaccines, small quantities of living organisms multiply within the recipient until an immune response cuts off replication. In contrast, inactivated vaccines and toxoids contain large quantities of antigens. In most recipients, a single dose of a live vaccine generally induces an immune response that closely parallels natural infection and induces long-term immunity. Killed (inactivated) vaccines, in contrast, often require multiple doses.

Passive Immunization

Passive immunization with use of immune globulins or antitoxins delivers preformed antibodies to provide temporary immunity. Immune globulins obtained from human blood may contain antibodies to a variety of agents, depending on the pool of human plasma from which they are prepared. Specific immune globulins are made from the plasma of donors with high levels of antibodies to specific antigens, such as tetanus immune globulin. Most immune globulins must be injected intramuscularly, although an intravenous preparation is also available. Antitoxins are solutions of antibodies derived from animals immunized with specific antigens (e.g., diphtheria antitoxin). Passive immunization usually is indicated to protect individuals immediately before anticipated exposure or shortly after known or suspected exposure to an infectious agent (Table 17-1), when active immunization either is not possible or has not been adequate.

Route and Timing of Vaccination

Each immunobiologic has a preferred site and route of administration. In adults, vaccines containing adjuvants should be injected intramuscularly, preferably in the deltoid muscle. For most adults, intramuscular injections should be administered with a 1- to 1½-inch, 22- to 25-gauge needle. Use of the buttocks is discouraged except when large volumes are required because of the potential for damage to the sciatic nerve and because of diminished immune response to some vaccines, such as hepatitis B, probably because of injection into fat rather than into muscle. Subcutaneous vaccines also are usually administered in the triceps area. In general, inactivated vaccines and toxoids can be given at the same visit at different sites. Live and inactivated vaccines usually can be administered at the same time. For example, measles, mumps, and rubella (MMR) vaccine can be administered at the same time as inactivated poliovirus vaccine and live attenuated varicella vaccine. In general, injected and intranasally administered live vaccines not delivered on the same day should be separated by at least 4 weeks to avoid interference. Orally administered live vaccines, such as oral typhoid vaccine, can be administered at any interval before or after live injected or intranasal vaccines. Immune globulin may interfere with the replication of injected live vaccine viruses; ideally, most live vaccines should be administered at least 2 weeks before or 3 to 11 months after immune globulin. Immune globulin does not interfere with the response to yellow fever vaccine and is not believed to interfere with orally or intranasally administered live virus vaccines.

Adverse Reactions

No vaccine is completely safe or completely effective. Hypersensitivity to vaccine components, such as animal proteins, antibiotics, preservatives, and stabilizers, can lead to local and systemic reactions ranging from mild to severe. Minor reactions are common, but randomized trials caution that prophylactic antipyretic drugs at the time of vaccination reduce antibody reactions and should not be given routinely. The egg protein contained in vaccines grown in chicken eggs (influenza and yellow fever vaccines) may cause reactions in persons severely allergic to eggs. In general, persons

TABLE 17-1 PASSIVE IMMUNIZATIONS FOR ADULTS

DISEASE	NAME OF MATERIAL	COMMENTS AND USE
Tetanus	Tetanus immune globulin, human	Management of tetanus-prone wounds in persons without adequate prior active immunization and treatment of tetanus
Cytomegalovirus	Cytomegalovirus immune globulin, intravenous	Prophylaxis for bone marrow and kidney transplant recipients
Diphtheria	Diphtheria antitoxin, equine	Treatment of established disease, high frequency of reactions to serum of nonhuman origin; in the United States, available only from CDC
Rabies	Rabies immune globulin, human	Postexposure prophylaxis of animal bites
Measles	Immune globulin, human	Prevention or modification of disease in contacts of cases, not for control of outbreaks
Hepatitis A	Immune globulin, human	Pre-exposure and postexposure prophylaxis for travelers and others who need protection before immunity can be achieved with hepatitis A vaccine
Hepatitis B	Hepatitis B immune globulin, human	Prophylaxis for needlestick or mucous membrane contact with HBsAg-positive persons, for sexual partners with acute hepatitis B or hepatitis B carriers, for infants born to mothers who are carriers of HBsAg, for infants whose mother or primary caregiver has acute hepatitis B
Varicella	Varicella-zoster immune globulin (VariZIG)	Persons with underlying disease and at risk for complications from chickenpox who have not had varicella or varicella vaccine and who are exposed to varicella; may be given after exposure to known susceptible adults, particularly if antibody negative. VariZIG is available under IND.
Vaccinia	Vaccinia immune globulin	Treatment of eczema vaccinatum, vaccinia necrosum, and severe inadvertent inoculations such as ocular vaccinia after vaccinia (smallpox) vaccination. Available only from the CDC.
Erythroblastosis fetalis	Rh immune globulin	Rh-negative women who give birth to Rh-positive infants or who abort
Hypogammaglobulinemia	Immune globulin, intravenous	Maintenance therapy
Idiopathic thrombocytopenic purpura	Immune globulin, intravenous	Therapy for acute episodes
Botulism	Bivalent A and B antitoxin, equine	Treatment of botulism; available through CDC
Snakebite	Antivenin, equine (North American coral snake antivenin)	Specific for North American coral snake, *Micrurus fulvius*
	Crotalidae, polyvalent	Effective for viper and pit viper bites, including rattlesnakes, copperheads, moccasins
Spider bite	Antivenin, equine	Specific for black widow spider, *Latrodectus mactans,* and other members of the genus

CDC = Centers for Disease Control and Prevention; HBsAg = hepatitis B surface antigen; IND = Investigational New Drug.

without anaphylactic-type allergies to eggs can be given these vaccines safely, but persons with anaphylactic reactions to eggs generally should not receive these vaccines except when it is absolutely necessary and then only under established protocols by physicians who are expert in such situations. Although measles and mumps vaccines are grown in chick embryo tissue culture, the risk of anaphylaxis even in persons with severe hypersensitivity to eggs is low, so they can be vaccinated without prior testing. Suspected adverse events temporally related to vaccinations should be reported to the Vaccine Adverse Events Reporting System (1-800-822-7967 or *www.vaers.hhs.gov*).

General Considerations

The major group that makes comprehensive, detailed recommendations regarding immunization of adults is the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC), which publishes its information in *Morbidity and Mortality Weekly Report* (also available at *http://www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm#print*). Immunizations for adults depend on age, lifestyle, occupation, and medical conditions. Two adult immunization schedules are available, one based on age group (Fig. 17-1 and E-Table 17-1) and one based on underlying risk (Fig. 17-2 and Table 17-2). All adults should have a primary series of tetanus and diphtheria toxoids with boosters of combined toxoids (Td) every 10 years. All adults should have a one-time dose of combined tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) followed by Td every 10 years. Persons born in or after 1957 should have evidence of immunity to measles, mumps, and rubella (e.g., documentation of vaccination or presence of antibodies considered compatible with protection). Vaccination of susceptible adolescents and adults against varicella is desirable. Pneumococcal polysaccharide vaccine (PPSV23) is indicated for all adults 65 years and older and younger adults with certain medical conditions that place them at high risk of complications. Influenza vaccination also is recommended annually for all persons 6 months of age or older. Health care workers exposed to blood or blood products should receive hepatitis B vaccine. Health care workers likely to come in contact with persons transmitting measles, mumps, rubella, or varicella should be immune to those diseases.

Immunocompromise

Patients with conditions that compromise their immune systems generally should not receive live attenuated vaccines. Such patients include those with immunodeficiency diseases, leukemia, lymphoma, and generalized malignant disease and those who are immunosuppressed from therapy with corticosteroids, alkylating agents, antimetabolites, and radiation. An exception is infection with human immunodeficiency virus (HIV). Asymptomatic patients should receive MMR vaccine. MMR should be considered for symptomatic patients with HIV infection; however, severely immunocompromised persons should not be vaccinated. Varicella vaccination (2 doses, 3 months apart) may be considered in HIV-infected persons with $CD4^+$ T-lymphocyte counts >200 cells/μL. Patients with leukemia in remission who have not been receiving any chemotherapy for at least 3 months may receive live virus vaccines. Short-course therapy (<2 weeks) with corticosteroids, alternate-day regimens with low to moderate doses of short-acting corticosteroids, and topical applications or tendon injections are not ordinarily contraindications to the administration of live vaccines.

Immunocompromised patients can receive inactivated vaccines and toxoids, although the efficacy of such preparations may be diminished. Patients with known HIV infection should receive pneumococcal vaccine and annual influenza vaccination.

Pregnancy

In general, live vaccines should not be given to pregnant women because of the theoretical concern that the vaccines could adversely affect the fetus. No significant adverse events attributable to vaccination of pregnant women with MMR or varicella have been documented; nevertheless, pregnant women should not receive MMR or varicella vaccine, and women who do receive these vaccines should wait 1 month before becoming pregnant. Poliomyelitis and yellow fever vaccines usually should not be given to pregnant women unless the risk of disease is substantial. Td vaccination is especially

Recommended Adult Immunization Schedule
UNITED STATES–2011

Note: These recommendations *must* be read with the footnotes that follow containing number of doses, intervals between doses, and other important information.

Recommended adult immunization schedule, by vaccine and age group

Vaccine ↓ / Age Group →	19–26 years	27–49 years	50–59 years	60–64 years	≥ 65 years
Influenza [1,*]	1 dose annually				
Tetanus, diphtheria, pertussis (Td/Tdap) [2,*]	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs				Td booster every 10 yrs
Varicella [3,*]	2 doses				
Human papillomavirus (HPV) [4,*]	3 doses (females)				
Zoster [5]				1 dose	
Measles, mumps, rubella (MMR) [6,*]	1 or 2 doses		1 dose		
Pneumococcal (polysaccharide) [7,8]	1 or 2 doses				1 dose
Meningococcal [9,*]	1 or more doses				
Hepatitis A [10,*]	2 doses				
Hepatitis B [11,*]	3 doses				

*Covered by the Vaccine Injury Compensation Program.

For all persons in this category who meet the age requirements and who lack evidence of immunity (e.g., lack documentation of vaccination or have no evidence of prior infection

Recommended if some other risk factor is present (e.g., based on medical, occupational, lifestyle, or other indications)

No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at htpp://www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. Information about filing a claim for vaccine injury is available through the U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, D.C. 20005; telephone 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination are also available at http://www.cdc.gov/vaccines, or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English or Spanish, 24 hours a day, 7 days a week.

FIGURE 17-1. Recommended adult immunization schedule, by vaccine and age group, United States, 2011. See E-Table 17-1 for footnotes. (From *http://www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm#print*.)

indicated for pregnant women who are not appropriately vaccinated to prevent neonatal tetanus in their infants. Vaccination is done best after the first trimester to avoid attribution to a vaccine of an adverse outcome of pregnancy that was only coincidental. Most pregnant women should not receive TdaP. In such cases, however, TdaP should be administered postpartum. All pregnant women should be screened for hepatitis B surface antigen (HBsAg). Children born to mothers with active HBsAg infection should receive hepatitis B vaccine and hepatitis B immune globulin within 12 hours of birth. Women who will be pregnant during the influenza season should receive inactivated influenza vaccine. Pregnant women have been shown to be at particularly high risk of complications from influenza and are at high priority to receive this vaccine to protect them.

INDIVIDUAL IMMUNOBIOLOGICS

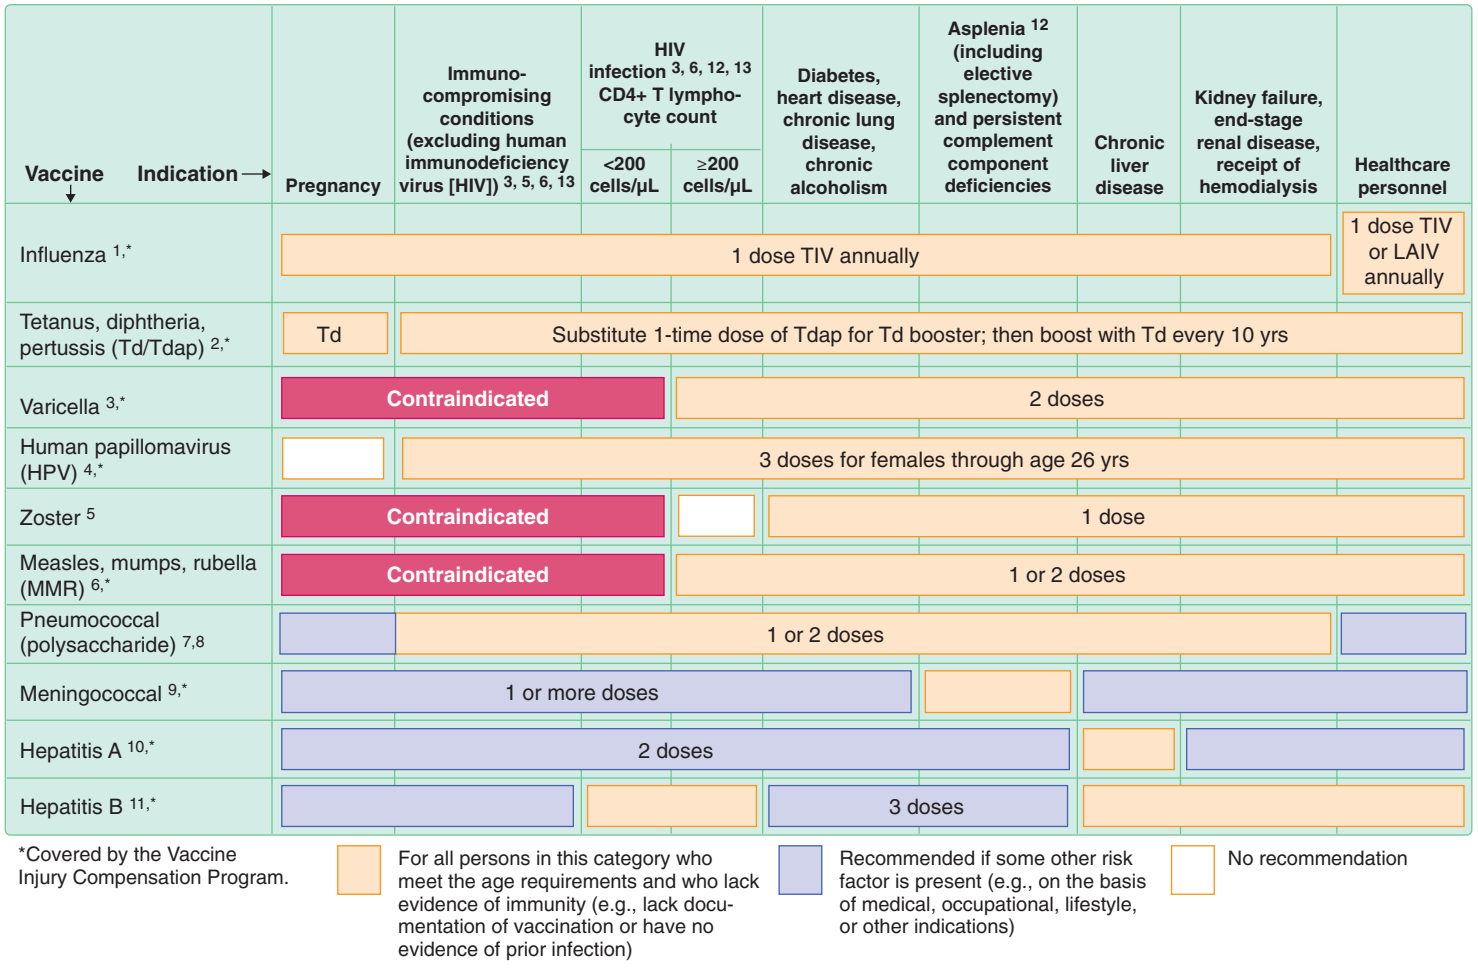
Hepatitis A

Two inactivated hepatitis A (Chapter 150) vaccines are available in the United States. Seroconversion rates after a single dose of either vaccine in persons older than 1 year exceed 95%. Antibody levels shown to be protective in animals develop in almost all persons.

Indications

The vaccine is indicated primarily for persons traveling to countries, generally the developing world, with high or intermediate endemicity for hepatitis A, but it is also recommended for other groups at high risk for infection or for development of severe hepatitis. In addition, vaccine is routinely recommended for children 12 to 23 months of age. Health care workers have not been shown to be at higher risk than the general population for hepatitis A and do not need routine immunization. Although food handlers are not at increased risk for hepatitis A compared with the general population, the consequences of infection or suspected infection in this group, which can lead to extensive public health investigations, may make vaccination cost-effective in some settings. Hepatitis A vaccine can be given to children 1 year of age or older to control outbreaks in communities with high rates of prior infection and be considered for communities with intermediate levels of prior infection (anti–hepatitis A seroprevalence of 10 to 25% by 5 years of age). Doses vary by age and product. All schedules call for a second dose at least 6 months after the first dose, with a permissible range for one of the products 18 months after the initial dose. Vaccines are not indicated for children younger than 1 year because adequate data on safety and efficacy are lacking.

Vaccines That Might Be Indicated for Adults Based on Medical and Other Indications



*Covered by the Vaccine Injury Compensation Program.

For all persons in this category who meet the age requirements and who lack evidence of immunity (e.g., lack documentation of vaccination or have no evidence of prior infection)

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)

No recommendation

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly indicated for adults ages 19 years and older, as of Febuary 4, 2011. For all vaccines being recommended on the adult immunization schedule, a vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statement from the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/pubs/aclp-list.htm).

FIGURE 17-2. Recommended adult immunization schedule, by vaccine and medical and other indications, United States, 2011. See E-Table 17-1 for footnotes. (From *http://www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm#print*.)

Side Effects

The most common side effect has been tenderness and soreness at the injection site. Although rare and more serious adverse events have been reported in temporal association with vaccination, a causal relationship has not been established.

Hepatitis B

Hepatitis B (Chapter 150) vaccine is the first vaccine that can prevent cancer (an estimated 800 persons per year in the United States die of hepatitis B–related liver cancer; many times more die in the developing world). It also can prevent acute and chronic complications of hepatitis B, including an estimated 4000 deaths annually from cirrhosis and 250 deaths annually from fulminant hepatic disease in the United States. Currently produced vaccines are derived from insertion of the gene for HBsAg into *Saccharomyces cerevisiae*. Hepatitis B vaccine, the first licensed vaccine made by use of recombinant techniques, produces adequate antibody responses in more than 90% of normal adults and more than 95% of normal infants, children, and adolescents when it is administered in a three-dose series. The dosage depends on the product, the age group, and the underlying clinical condition and can be determined by consulting the package insert. The duration of vaccine-conferred immunity is not known, although follow-up of vaccinees for more than 16 years indicates persistence of protection against clinically significant infections (i.e., detectable viremia and clinical disease). Booster doses are not currently recommended. Vaccine must be injected intramuscularly, preferably in the deltoid.

Indications

Hepatitis B vaccine is indicated for adults at high risk of infection (see Fig. 17-1 and E-Table 17-1). Because strategies targeting hepatitis B vaccine use only to high-risk populations have not had a significant impact on hepatitis B incidence, universal vaccination is recommended for infants and for all adolescents who have not been previously vaccinated. Universal screening for HBsAg is recommended for all pregnant women; administration of three doses of vaccine and one dose of hepatitis B immune globulin is recommended for infants of acutely or chronically infected mothers.

Side Effects

The major side effect is soreness at the injection site. Alopecia, which is usually reversible, has been reported rarely. Hepatitis B vaccine has not been shown to induce multiple sclerosis in controlled studies and has not been shown to exacerbate illness in patients with multiple sclerosis who are vaccinated.

Human Papillomavirus

Two human papillomavirus (HPV) vaccines are licensed. Both vaccines contain the L1 capsid protein of types 16 and 18, which account for about 70% of cases of cervical cancer. The quadrivalent vaccine also contains types 6 and 11, which are the most common causes of anogenital warts. Routine vaccination of 11- to 12-year-old girls is recommended in a three-dose schedule. The vaccine should be administered at 0, 1 to 2, and 6 months. Catch-up

TABLE 17-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS AND PRECAUTIONS	COMMENTS
Anthrax	Anthrax vaccine, adsorbed, an inactivated vaccine	Pre-exposure prophylaxis of persons at high risk of exposure (e.g., military, certain laboratory workers) Consider with antibiotics for postexposure prophylaxis	0.5-mL dose IM at 0, 4, and 6 wk and 12 and 18 mo Manufacturer recommends booster annually thereafter If used after exposure, 3 doses at 0, 2, and 4 wk with antibiotics for at least 7-14 days after third dose	Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	Effectiveness against aerosol exposure inferred primarily from animal data Limited data on the benefits of postexposure use
Diphtheria	Tetanus and diphtheria toxoids combined	All adults	Two doses IM 4 wk apart, third dose 6-12 mo after second dose for primary series Booster every 10 yr No need to repeat if schedule is interrupted	History of neurologic reaction after a previous dose Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution	Tetanus and diphtheria toxoids combined with acellular pertussis vaccine (Tdap) preferred as one-time booster for all persons through 64 yr
Hepatitis A	Inactivated hepatitis A vaccine	Travelers to highly or intermediately endemic countries Men who have sex with men Illegal drug users (injection and noninjection) Persons who work with hepatitis A virus–infected primates or who do research with the virus Persons with chronic liver disease Recipients of clotting factors	Two doses at least 6 mo apart for persons aged ≥1 yr	Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	Recommended for all children Should be considered for outbreak control
Hepatitis B	Inactivated hepatitis B virus subunit vaccine containing HBsAg	Adolescents Health care and public safety workers potentially exposed to blood Clients and staff of institutions for the developmentally disabled Hemodialysis patients Men who have sex with men Users of illicit injectable drugs Recipients of clotting factors Household and sexual contacts of HBV carriers Inmates of long-term correctional facilities Heterosexuals treated for sexually transmitted diseases or with multiple sexual partners Travelers with close contact for ≥6 mo with populations with high prevalence of HBV carriage	Three doses IM at 0, 1, and 6 mo	Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	Pregnancy is not a contraindication Health care workers who have contact with patients or blood, sexual contacts of persons with chronic HBV infection, hemodialysis patients and other immunosuppressed persons, and recipients of clotting factor concentrates should be tested 1-2 mo after vaccination to determine serologic response
Human papilloma-virus	Inactivated L1 capsid proteins of types 6, 11, 16, and 18 (quadrivalent) and types 16 and 18 (bivalent)	Females at 11-12 yr; catch-up vaccination of females through 26 yr Males 9 through 26 yr for genital warts	Three 0.5-mL doses IM at 0, 1 to 2, and 6 mo	Severe allergic reaction to a vaccine component or to a prior dose Vaccine is not recommended for pregnant women	The vaccine will not protect against existing infections Because the types in the vaccine are not responsible for about 30% of infections associated with cervical cancer, screening for cancer should occur as for unvaccinated women
Influenza	Inactivated virus vaccine	All adults, with greatest priority for those ≥65 yr old, persons with underlying medical conditions, pregnant women, health care workers, and persons with close contact with children <5 years of age	Annual vaccination; see annual ACIP recommendation	Severe allergic reaction to an influenza vaccine component (including eggs) or after a prior dose Moderate or severe acute illness is a precaution to vaccination GBS within 6 wk of prior dose of influenza vaccine	Optimum timing for vaccination is October and November However, vaccination can occur in December and later, particularly for health care workers and persons at high risk for complications who were not vaccinated earlier Only one dose of influenza vaccine per season is recommended for adults

TABLE 17-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS AND PRECAUTIONS	COMMENTS
Influenza (cont'd)	Live attenuated influenza virus	Persons 2 through 49 yr without underlying conditions that place them at high risk of complications from influenza	Annual vaccination; see annual ACIP statement Administered intranasally	Persons <2 yr or ≥50 yr Underlying disorders that place them at high risk of influenza complications History of GBS within 6 wk of prior dose of influenza vaccine Pregnant women Hypersensitivity to eggs or components of vaccine	Can be used for household contacts and health care workers caring for patients without severe immunocompromise
Japanese encephalitis	Inactivated Japanese encephalitis virus vaccine	Travelers to Asia spending at least 1 mo in endemic areas during transmission season	Two 0.5-mL doses IM on days 0 and 28 for persons 18 yr and older	Pregnancy	
Measles	Live virus vaccine	All adults born after 1956 without history of live vaccine on or after first birthday, physician-diagnosed measles, or detectable measles antibody Persons born before 1957 generally can be considered immune	One dose sufficient for most adults; 2 doses at least 1 mo apart indicated for persons entering college or medical facility employment, traveling abroad, or at risk of measles during outbreaks	Altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) Immune globulin or other blood products within prior 3-11 mo, depending on dose of immune globulin or blood product received Untreated tuberculosis Anaphylactic hypersensitivity to neomycin or gelatin Pregnancy Thrombocytopenia	Persons with anaphylactic allergies to eggs may be vaccinated (see text) Vaccine should be administered to persons with asymptomatic HIV infection and should be considered for patients except those with severe immunocompromise
Meningococcal disease (2 vaccines)	1. Meningococcal conjugate vaccines containing polysaccharide of serogroups A, C, W135, and Y (age 2-55 yr) 2. Polysaccharide vaccine containing tetravalent A, C, W135, and Y (ages 56 yr and older)	All 11- to 18-year-old persons and all persons with persistent complement component deficiencies, anatomic or functional asplenia, persons who will travel to areas with hyperendemic or epidemic diseases; certain laboratory workers; may be useful during localized outbreaks	One dose with revaccination at age 16 yr of children who receive conjugate vaccine at 11-12 yr of age and every 5 yr for persons at high risk	1. Allergic reactions to a component of the vaccine including diphtheria toxoid and latex	Conjugate vaccine is preferred to polysaccharide alone for persons aged 2 through 55 yr
Mumps	Live virus vaccine	All adults born after 1956 without history of live vaccine on or after first birthday, physician-diagnosed mumps, or detectable mumps antibody Persons born before 1957 generally can be considered immune	One dose sufficient for most adults; 2 doses at least 1 mo apart indicated for persons entering college or medical facility employment, or traveling abroad	Altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) Immune globulin or other blood products within prior 3-11 mo Anaphylactic hypersensitivity to neomycin or gelatin Pregnancy Thrombocytopenia if administered with measles vaccine	Although persons born after 1957 are generally immune, vaccine can be given to adults of all ages and may be particularly indicated for postpubertal males who are thought to be susceptible Persons with anaphylactic allergies to eggs may be vaccinated
Pertussis	Adult preparation of pertussis antigens combined with tetanus and diphtheria toxoids (Tdap)	All 11- to 12-year-olds Catch-up vaccination for all persons 13-64 yr of age Preferred interval of 5 yr from prior dose of Td but may be given at shorter intervals if risk of pertussis is high	One dose	Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	Two preparations are available, one licensed for 10- to 64-year-olds, one for 11- to 64-year-olds Administer one dose to persons 65 yr of age or older who have not previously received Td and who anticipate contact with infants younger than 1 yr of age

TABLE 17-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS AND PRECAUTIONS	COMMENTS
Pneumococcal disease	23-Valent polysaccharide vaccine	Adults with cardiovascular disease, pulmonary disease (including asthma), diabetes mellitus, alcoholism, cirrhosis, cerebrospinal fluid leaks, splenic dysfunction or anatomic asplenia, Hodgkin's disease, lymphoma, multiple myeloma, chronic renal failure, nephrotic syndrome, immunosuppression, HIV infection, cigarette smokers 19 yr and older High-risk populations such as certain Native Americans and all adults ≥65 yr	One dose IM or SC; a second dose should be considered ≥5 yr later for adults at high risk of disease (e.g., asplenic patients) and those who lose antibody rapidly (e.g., nephrotic syndrome, renal failure, transplant recipients) Revaccinate adults who received a first dose when <65 yr who are now ≥65 yr and who received their vaccine at least 5 yr earlier	Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	Conjugate pneumococcal vaccine is not indicated for adults
Poliomyelitis	Inactivated poliovirus vaccine	Certain adults who are at greater risk of exposure to wild poliovirus than the general population, including travelers to countries where poliomyelitis is epidemic or endemic or specific populations with disease caused by wild poliovirus	For unvaccinated adults, two doses SC 4 wk apart and a third dose 6-12 mo after the second; if <4 wk available before protection is needed, a single dose of IPV For incompletely immunized adults, complete primary series that consists of three doses of IPV or prior OPV; no need to restart interrupted series A single dose of IPV can be given to adults who previously received a primary series but now are at high risk, such as travel to an endemic area	On theoretical grounds, pregnant women should not receive IPV, but if immediate protection is needed, IPV can be used Severe allergic reaction to a vaccine component or after a prior dose Moderate or severe acute illness is a precaution to vaccination	
Rabies	Inactivated vaccine, HDCV or PCEC	High-risk persons, including animal handlers, selected laboratory and field workers, and persons traveling for ≥1 mo to areas with high risk of rabies	Pre-exposure prophylaxis: three doses of 1 mL IM on days 0, 7, and 21 or 28	History of severe hypersensitivity reaction	Further doses needed after exposure
Rubella	Live virus vaccine	Adults, particularly women of childbearing age, who lack history of rubella vaccine and detectable rubella-specific antibodies in serum Males and females in institutions where rubella outbreaks may occur, such as hospitals, the military, and colleges Persons born before 1957, except women who can become pregnant, generally can be considered immune	One dose SC	Pregnancy, altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) Immune globulin or other blood products within the 3-11 mo before vaccination Anaphylactic hypersensitivity to neomycin Administration of blood products should not contraindicate postpartum vaccination Thrombocytopenia if administered with measles vaccine	Women should be counseled to avoid pregnancy for 1 mo after vaccination

TABLE 17-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS AND PRECAUTIONS	COMMENTS
Smallpox	Live vaccinia virus	Persons working with orthopox viruses Members of public health and health care response teams	One dose intracutaneously with a bifurcated needle Boosters every 10 yr and perhaps every 3 yr for persons working with virulent orthopox viruses	History or presence of eczema or other acute, chronic, or exfoliative skin condition Immunosuppression or pregnancy in patient or a close household or personal contact History of heart disease Breast-feeding Age <1 yr Allergy to a vaccine component No contraindications if exposed to smallpox	Some complications of vaccination are treatable with vaccinia immune globulin Vaccine is effective 3-4 days after exposure to variola and perhaps longer to prevent or to modify the illness Serious adverse events are rare but significant, including eczema vaccinatum, progressive vaccinia, myopericarditis, autoinoculation, and encephalitis Vaccinia is transmissible
Tetanus	Tetanus and diphtheria toxoids combined	All adults	Three doses IM needed for primary series: two doses 4 wk apart, third dose 6-12 mo after second dose Booster every 10 yr; no need to repeat if schedule is interrupted	History of neurologic or severe allergic reaction after a prior dose	Special recommendations for wound treatment (see text) Persons with GBS within the first 6 wk after immunization, particularly adults who received a prior primary series, probably should not be revaccinated in most circumstances Tetanus and diphtheria toxoids combined with acellular pertussis (Tdap) vaccine preferred for booster at age 11-12 yr One-time booster of Tdap for persons through 64 yr
Typhoid fever	Vi capsular polysaccharide vaccine Live attenuated Ty21a oral vaccine	Travelers to areas where the risk of prolonged exposure to contaminated food and water is high May be considered for family and intimate contacts of carriers and laboratory workers who work with *Salmonella typhi*	Vi polysaccharide vaccine: one dose IM 0.5 mL, boosters every 2 yr Oral vaccine: four doses on alternate days, repeat series every 5 yr if risk continues	Severe local or systemic reaction to a prior dose Ty21a vaccine should not be administered to persons with altered immunity or those receiving antimicrobial agents	Efficacy only 50-77% Food and water precautions essential
Varicella: chickenpox strain	Attenuated Oka strain of varicella virus	All persons without evidence of varicella immunity especially health care personnel, childbearing-age women, and persons with household or other contact with persons at high risk of complications of varicella (e.g., susceptible immunosuppressed persons)	Two 0.5-mL SC doses 4-8 wk apart for persons ≥13 yr A second dose is recommended for all persons who previously received one dose	Immunocompromise Pregnancy Allergy to vaccine components	Adults with a history of prior clinician-diagnosed or verified varicella can be considered immune Vaccine virus has rarely been transmitted to contacts from healthy vaccinees in whom rash developed Women who receive vaccine should not become pregnant for 1 mo
Varicella: zoster	Attenuated Oka strain of varicella virus, approximately 14 times more potent than varicella vaccine	Persons ≥60 years of age	One 0.65-mL dose SC	Immunocompromise Pregnancy Allergy to vaccine components	May be administered regardless of a prior history of shingles
Yellow fever	Live attenuated virus (17D strain)	Persons living or traveling in areas where yellow fever exists	One dose, booster every 10 yr	Immunocompromised persons History of anaphylactic allergies to eggs Pregnancy on theoretical grounds, although may be given if risk is high	Fever, jaundice, and multiple-organ system failure (viscerotropic disease) have been rarely reported in first-time recipients of 17D-derived yellow fever vaccinations Vaccinate only persons traveling to areas endemic to yellow fever

*See the text and package inserts for further details, particularly regarding indications, dosage, mode of administration, side effects, and adverse reactions and contraindications.
ACIP = Advisory Committee on Immunization Practices; GBS = Guillain-Barré syndrome; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HDCV = human diploid cell vaccine for rabies; HIV = human immunodeficiency virus; IM = intramuscularly; IPV = inactivated poliovirus vaccine; MMR = measles, mumps, and rubella vaccine; OPV = live trivalent oral poliovirus vaccine; PCEC = purified chick embryo cell culture rabies vaccine; SC = subcutaneously.

vaccination should be undertaken for females up through 26 years of age. Recipients of HPV vaccine should follow the same recommendations for Papanicolaou (Pap) smear screening as unvaccinated females. Persons with prior abnormal Pap smears or genital warts may be vaccinated to prevent persistent infection with types of HPV that are not in the vaccine. In 2009, the U.S. Food and Drug Administration (FDA) also licensed the quadrivalent vaccine for males, 9 through 26 years of age, for prevention of genital warts.

Side Effects

The most common reactions are local pain, swelling, and erythema, which may, in part, be explained by the aluminum-containing adjuvant rather than the L1 capsid protein. There is a slightly higher incidence of fever within 15 days of vaccination in vaccine recipients compared with placebo recipients.

Influenza

The two available influenza vaccines for seasonal influenza are the inactivated trivalent influenza vaccine (TIV) and the live attenuated influenza vaccine (LAIV). TIV, which contains split viruses of three major antigenic types, A (H3N2), A (H1N1), and B, is administered intramuscularly. LAIV, which consists of three cold-adapted, temperature-sensitive attenuated viruses, one for each of the expected circulating strains, is administered intranasally. LAIV is prepared by use of attenuated parent viruses that have been reassorted with circulating strains to contain six internal genes from the parent virus and genes for the surface hemagglutinin and neuraminidase of an A (H3N2), A (H1N1), or B strain. In 2009, a novel H1N1 virus emerged and caused a global pandemic. The 2009 H1N1 split virus vaccine is now the H1N1 component of the annual influenza vaccine.

Indications

Annual influenza (Chapter 372) vaccination with TIV is indicated for all adults but with a special emphasis on persons at high risk of complications from the disease: persons with chronic cardiopulmonary disorders, residents of nursing homes or other long-term care facilities, persons 50 years of age or older, patients with other chronic diseases (e.g., diabetes mellitus, kidney dysfunction, hemoglobinopathies, and immunosuppression) who have required regular medical follow-up or hospitalization in the prior year, adults and children who have any condition (e.g., cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function or the handling of respiratory secretions or that can increase the risk for aspiration, and children receiving long-term aspirin therapy. Women who will be pregnant during the influenza season (usually late December through mid-March) also should be vaccinated. To reduce transmission of influenza to high-risk patients, health care workers and household contacts of high-risk patients should also be vaccinated annually, including contacts of children younger than 5 years of age. Annual vaccination is also recommended for all children 6 months through 18 years.

LAIV is licensed only for nonpregnant persons aged 2 through 49 years without underlying conditions that place them at high risk of complications from influenza. LAIV can be used for contacts of high-risk patients, if the contacts are of the appropriate age. LAIV, for theoretical concerns about live virus transmission, is not recommended for contacts of severely immunosuppressed patients such as patients with bone marrow transplants but can be given to contacts of persons with mild to moderate immunologic impairment.

The efficacy of TIV varies with the host's condition and the degree to which antigens in the vaccine match viruses in circulation the following season. Provided the match is good, the vaccine's efficacy is usually 70 to 90% in normal healthy young adults. Efficacy is substantially lower, often between 30 and 40%, in the institutionalized elderly; nevertheless, it seems to be 60 to 80% protective against pneumonia and death. LAIV has been found to be more than 85% effective in young children, even in a year when the circulating strain had antigenically drifted from the vaccine strain. Similar effects were seen in challenge studies in adults.

Ideally, seasonal vaccines should be administered as soon as they are available. If vaccine is available in December and January, vaccination should continue because it still can offer protection for many individuals. A review of influenza seasons from 1976-77 through 2008-09 documented that peak activity did not occur until January or later in more than 80% of those seasons and until February or later in more than 60%.

Side Effects

Persons with anaphylactic allergy to eggs generally should not be immunized. The most common side effect of TIV is soreness at the injection site. Fever, malaise, and myalgia may begin 6 to 12 hours after vaccination and persist for 1 to 2 days, although such reactions are most common in children exposed to vaccine for the first time. Severe allergic reactions are rare. If current influenza vaccines cause Guillain-Barré syndrome, it is likely to be rare, on the order of one case per 1 million doses. The most common adverse events after LAIV in adults are runny nose, headache, and sore throat.

Measles

Indications

Measles (Chapter 375) immunization is recommended for all persons born in or after 1957 who lack evidence of prior physician-diagnosed measles or laboratory evidence of immunity or appropriate vaccination. Before 1989, appropriate vaccination consisted of a single dose of live vaccine administered on or after the first birthday. Since then, a routine two-dose schedule has been recommended: the first dose, which is 93 to 98% effective, at 12 to 15 months of age, and the second dose at entry to primary school. All children from kindergarten through the 12th grade should have a second dose. Most adults are considered to have been appropriately vaccinated if they received one dose of vaccine administered on or after their first birthday. Some adults who are at increased risk of measles (health care workers with direct contact with patients, students in college, international travelers) should receive a second dose of vaccine, however, unless they have documentation of serologic evidence of immunity. Persons embarking on foreign travel ideally should have received two doses or have other evidence of measles immunity. Persons born before 1957 are usually immune as a result of natural infection and do not require vaccination, although vaccination is not contraindicated if they are believed to be susceptible.

During outbreaks of measles in institutions, all persons at risk who have not received two doses or who lack other evidence of measles immunity should be vaccinated. Measles vaccine is usually administered along with mumps and rubella vaccines as MMR to ensure immunity against all three diseases. Individuals already immune to one or more of the components may receive MMR without harm.

Measles vaccine is contraindicated for pregnant women on theoretical grounds, for persons with moderate to severe acute febrile illnesses, and for persons with altered immunocompetence, except those with HIV infection who are not severely immunocompromised. Patients with anaphylactic reactions to eggs can be vaccinated without prior skin testing.

Side Effects

In approximately 5 to 15% of susceptible recipients of measles vaccine, temperatures of 39.4° C or higher develop 5 to 12 days after vaccination and last 1 to 2 days. Transient rashes develop in about 5%. Thrombocytopenic purpura has been reported rarely after MMR. The overall rate of reactions after the second dose of a measles-containing vaccine is substantially lower than after the first dose. Encephalopathy or encephalitis after measles vaccination has been reported at a rate lower than the background or expected rate.

Meningococcal Vaccines

Three quadrivalent meningococcal polysaccharide vaccines against disease caused by serogroups A, C, Y, and W135 are available: meningococcal polysaccharide vaccine (MPSV4), which consists of 50 μg of polysaccharide of each of the four serogroups and is licensed for persons 2 years of age and older, and two meningococcal conjugate vaccines (MCV4). One conjugate consists of 4 μg of each polysaccharide covalently linked to 48 μg of diphtheria toxoid and licensed for persons 2 to 55 years of age. The other conjugate consists of polysaccharide linked to CRM_{197}. The four serogroups in each vaccine account for approximately two thirds of meningococcal disease in the United States and about 75% of the disease in persons 11 years of age or older (Chapter 306). Serogroup A and C polysaccharide vaccines have had 85 to 100% efficacy in epidemic settings, whereas polysaccharide vaccines for the other groups have documented good immunogenicity in adults. Meningococcal conjugate vaccine type C (MCV-C) has been associated with an estimated effectiveness of 88 to 98% in the year following vaccination in the United Kingdom, where it has been used widely. In addition, MCV-C has reduced colonization by 66% and decreased disease among unvaccinated persons by 67% in 1- to 17-year-olds and by 35% among those older than 25

years. In contrast to polysaccharide vaccines, conjugate vaccines induce immunologic memory, result in higher and more durable levels of high-avidity antibodies, and have been documented to induce herd immunity. The duration of immunity for both MPSV4 and MCV4 is thought to be about 5 years.

Indications

Routine vaccination with a single dose of MCV4 is recommended for all adolescents at 11 through 18 years of age who have not been previously vaccinated and for college freshmen who will live in dormitories. Vaccination is also recommended for very-high-risk persons, that is, those with persistent complement component deficiencies, persons with splenic dysfunction or without a spleen, microbiologists with frequent exposure to *Neisseria meningitidis* in culture, and persons who travel to or live in areas with hyperendemic or epidemic disease (e.g., the "meningitis belt" of sub-Saharan Africa, stretching from Mauritania to Ethiopia). MCV4 can be used for persons 2 to 10 years of age with high-risk conditions. It is not recommended routinely for this age group. For persons older than 55 years with an indication for vaccine, MPSV4 should be used. Meningococcal vaccination may be useful during localized epidemics of serogroups in the vaccine.

Re-vaccination is indicated at age 16 in children initially vaccinated between 11 and 12 years of age. For children initially vaccinated after age 12 years, re-vaccination recommendations are still being developed *(www.ccc.gov/vaccines)*. For very high-risk persons, re-vaccination is recommended every 5 years.

Side Effects

The major side effects of MPSV4 are local reactions lasting 1 to 2 days. The incidence of local reactions and low-grade fever is slightly higher after MCV4 than with MPSV4. An excess risk of 1.25 cases of Guillain-Barré syndrome per million doses has been noted with the vaccination, although further studies have cast doubt on a causal association.

Mumps

Indications

Mumps (Chapter 377) vaccine is indicated for all persons, especially susceptible males, without evidence of immunity. For most adults, such evidence consists of a prior history of vaccination on or after the first birthday, physician-diagnosed mumps, or laboratory evidence of immunity. For adults at high risk, including health care workers, international travelers, and students at post–high school educational institutions, two doses of mumps vaccine constitute acceptable evidence of immunity. Most persons born before 1957 can be considered immune as a result of natural infection, although vaccination is not contraindicated if such persons are thought to be susceptible.

Side Effects

Adverse events after the Jeryl Lynn strain of mumps vaccine, the strain used in the United States, are uncommon—fever, parotitis, and allergic manifestations. Thrombocytopenic purpura has been reported rarely in persons administered MMR. Mumps vaccine is contraindicated for pregnant women on theoretical grounds, for persons with moderate to severe acute febrile illnesses, and for persons with altered immunocompetence. When combined with measles vaccine, it may be given to persons with asymptomatic HIV infection and considered for persons with symptomatic infection if they are not severely immunocompromised. Patients with anaphylactic reactions to eggs can be vaccinated without skin testing (see Measles earlier).

Pertussis Vaccine

In 2005, two vaccines were licensed for boosting immunity to pertussis. Both vaccines are combined with the adult preparation of tetanus and diphtheria toxoids and have a reduced content of pertussis antigens compared with the childhood pertussis-containing vaccines (Tdap). Boostrix (GlaxoSmithKline), which is licensed for adolescents and adults 10 through 64 years of age, contains three pertussis antigens—toxoid (PT), filamentous hemagglutinin (FHA), and pertactin (PRN). Adacel (Sanofi Pasteur, Inc.), which is licensed for 11- through 64-year-olds, contains five pertussis antigens, PT, FHA, PRN, and two fimbriae. Both vaccines, when administered to previously vaccinated adolescents and adults, induce serologic responses that are comparable to those induced during childhood vaccination with vaccines that have been proved effective. Adverse events, usually local reactions, are similar with the adult preparation of tetanus and diphtheria toxoids (Td) alone. A single dose of Tdap is indicated for all adolescents at 11 to 12 years of age. Older adolescents should receive Tdap instead of Td if they have not received an adolescent Td booster. Tdap can be given at any interval. All adults younger than 65 years should receive a single dose of TdaP to replace a Td booster. Persons are 65 years and older who anticipate contact with an infant should receive a single dose of Tdap.

Pneumococcal Vaccine

Pneumococcal polysaccharide vaccine consists of purified polysaccharide capsular antigens from the 23 types of *Streptococcus pneumoniae* that are responsible for 85 to 90% of the bacteremic disease in the United States (Chapter 297). Most adults, including elderly patients and those with alcoholic cirrhosis and diabetes mellitus, have a two-fold or greater rise in type-specific antibodies within 2 to 3 weeks of vaccination. Although the serologic response is generally acceptable, estimates of vaccine efficacy in preventing disease vary widely. Efficacy may be lower in some patients, such as patients with alcoholic cirrhosis or Hodgkin's disease. There is good evidence that vaccination is approximately 60% effective against bacteremic pneumococcal disease, which accounts for an estimated 50,000 cases annually. Evidence regarding efficacy against pneumonia in high-risk populations is not clear, however.

Indications

The preponderance of information supports the use of pneumococcal vaccine in high-risk populations, including all persons older than 65 years. Two groups recently added to those recommended for vaccination include persons 19 years or older who smoke cigarettes or those who have asthma. Special efforts should target hospitalized patients. Approximately two thirds of patients who are admitted later with pneumococcal disease had been hospitalized for other reasons within the preceding 5 years.

Immunity may decrease 5 years or more after initial vaccination; a single booster dose should be considered at that time for adults at highest risk of disease, such as asplenic patients, and for adults who lose antibody rapidly, such as patients with nephrotic syndrome or renal failure. Persons older than 65 years who received a dose more than 5 years earlier when they were younger than 65 years should be revaccinated.

Side Effects

Local reactions are frequent. Less than 1% of vaccinees experience severe local reactions or systemic illness, such as fever and malaise. Severe events such as anaphylaxis are rare. Because of the rarity of severe reactions in revaccinated patients, persons with indications for vaccination but with unknown histories of prior vaccination should be vaccinated.

A pneumococcal conjugate vaccine in which the polysaccharides of 13 types are covalently linked to a protein carrier was licensed and recommended for universal use in children. This vaccine, which covers substantially fewer types than the 23-valent polysaccharide vaccine, is not approved for persons 9 years of age or older. Widespread vaccination of children in the United States has led to substantial reductions of invasive pneumococcal disease in adults, suggesting that children are the source for many adult infections. Trials of conjugate vaccines in adults are ongoing.

Poliomyelitis

The last documented cases of indigenously acquired poliomyelitis (Chapters 387 and 423) caused by wild polioviruses in the United States were reported in 1979. In 2000, an all inactivated poliovirus vaccine (IPV) schedule was recommended in the United States; this vaccine replaced the live attenuated oral poliovirus vaccine (OPV), which, although it had eliminated wild poliovirus in the United States, caused about eight cases per year on average among OPV recipients or their contacts. IPV is the only vaccine available in the United States. OPV is still the vaccine used in most countries around the world, however. Between 1988, when the goal was announced to eradicate wild poliovirus from the world, and 2010, cases of poliomyelitis worldwide decreased by an estimated 99%. Four countries (Nigeria, India, Pakistan, and Afghanistan) have never interrupted endemic transmission. However, because of spread from Nigeria and India, 16 countries were reinfected in 2010. Efforts to eradicate polio globally continue.

Indications

Routine vaccination of persons 18 years of age or older is not warranted given the small risk of exposure to wild virus in the United States. The major

indication for adult vaccination is travel to areas where wild poliovirus is endemic or epidemic. Previously unvaccinated adults should receive IPV. Adult travelers who have histories of partial vaccination should complete a primary series of three doses with IPV. Adults who formerly received three doses of OPV or IPV should receive a single booster of IPV. A primary series of IPV consists of three doses. A fourth dose is administered to children at school entry.

Side Effects

No serious side effects of IPV have been reported.

Rabies

Indications

Rabies (Chapter 422) vaccine is indicated for pre-exposure prophylaxis of high-risk persons, including animal handlers, selected laboratory and field workers, and persons traveling for more than 1 month to areas where rabies is a constant threat. The pre-exposure regimen consists of three 1-mL intramuscular injections on days 0, 7, and 21 or 28 for all rabies vaccines. Postexposure treatment depends on prior exposure to vaccine (Chapter 422). Persons being treated for the first time should be given four doses at days 0, 3, 7, and 14. Human rabies immune globulin is also indicated for previously unvaccinated persons who are exposed.

Rubella

Indications

Rubella (Chapter 376) vaccine is indicated for susceptible adults born in 1957 or later and for susceptible women of any age who are considering becoming pregnant. Persons without a prior history of vaccination on or after the first birthday or laboratory evidence of immunity should be considered susceptible. A single dose of vaccine is 95% or more effective. Many persons receive two doses of rubella vaccine by the two-dose schedule of MMR.

Side Effects

Follow-up of susceptible pregnant women who received rubella vaccines within 3 months of the estimated date of conception has failed to reveal any evidence of defects compatible with congenital rubella syndrome in their offspring. Nevertheless, vaccine is contraindicated in pregnant women on theoretical grounds, and conception should be delayed for 1 month after rubella vaccination.

Adverse reactions occur only in susceptible persons. Arthralgia, usually of the small peripheral joints, develops in 40% of susceptible adults, and frank arthritis develops in 10 to 20%. Joint symptoms usually begin 1 to 3 weeks after vaccination and persist for 1 day to 3 weeks. Chronic recurrent or persistent joint symptoms have developed rarely after vaccination, but controlled studies have shown that the incidence of these events in vaccinees is similar to that in nonvaccinees. Other infrequent adverse events include transient peripheral neuritis and pain in the arms and legs. Thrombocytopenic purpura has been reported rarely when rubella vaccine is administered as MMR. Rubella vaccine is contraindicated for persons with moderate to severe acute illnesses and for persons with reduced immunocompetence. When given with measles vaccine, it may be administered to persons with asymptomatic HIV infection and considered for persons with symptomatic infection without severe immunocompromise. Rubella vaccine is grown in human diploid cells and can be administered without problems to persons with allergy to eggs.

Tetanus and Diphtheria

Tetanus (Chapter 304) toxoid is one of the most effective immunizations, with more than 95% protection after a primary series. A primary series consists of three doses. In persons aged 7 years or older, it should always be used in combination with diphtheria (Chapter 300) toxoid (Td), which is more than 85% effective in preventing disease. Combinations also including pertussis antigens (Tdap) are preferred to Td for routine immunization of adolescents. Doses need not be repeated if the schedule is interrupted. A booster dose of Td is recommended every 10 years. An easy way to remember is to schedule immunization at the middle of each decade (e.g., 25 years, 35 years).

Indications

After a wound, persons of unknown immunization status or persons who have received fewer than three doses of tetanus toxoid should receive a dose of Td regardless of the severity of the wound. Td also is indicated for persons who have previously received three or more doses if more than 10 years has elapsed since the last dose, in the case of clean and minor wounds, and if more than 5 years has elapsed for all other wounds. Persons who have never received a dose of TdaP should receive it in place of Td for wound management. Tetanus immune globulin should be administered simultaneously at a separate site to persons who have not received at least three doses of toxoid and who have wounds that are not clean and minor.

Side Effects

Most reactions to Td consist of local inflammation and low-grade fever. Guillain-Barré syndrome and brachial neuritis rarely have been associated with tetanus toxoid.

Varicella: Chickenpox

A live attenuated varicella vaccine (Oka strain) was licensed in 1995. A combination measles-mumps-rubella-varicella vaccine was licensed in 2005. One dose of the vaccine protects 70 to 90% of recipients against any disease and more than 95% of recipients against severe disease. Although some studies have suggested immunity may wane with increasing time since vaccination, others have not. Use of vaccine has been associated with dramatic decreases in the incidence of varicella. Breakthrough infections in persons who have previously seroconverted have been reported. Such breakthroughs are typically mild and average fewer than 50 lesions compared with several hundred lesions in unvaccinated persons with varicella. Breakthrough illnesses do not seem to increase in incidence or severity with increasing time since vaccination, a finding compatible with long-term protection after initial vaccination. Because of persistent transmission of varicella, a two-dose schedule is recommended for all persons.

Indications

Varicella vaccine is indicated routinely for all children without a contraindication. A two-dose schedule is recommended, generally at 12 to 15 months of age and 4 to 6 years of age. For persons who previously received a single dose, catch-up vaccination with a second dose is recommended, provided at least 3 months have elapsed since the first dose. Persons who received a second dose at least 28 days after the first dose do not need a third dose. Persons 13 years or older without evidence of immunity to varicella should receive two doses at least 4 weeks apart. Persons with a clinician-diagnosed or verified history of varicella disease can be considered immune and do not need vaccination. Although a negative or unknown history of disease is predictive of susceptibility in children, many adults with such histories are immune. Serologic screening of adults in some situations may be cost-effective, provided that identified susceptible adults are vaccinated. Serologic testing is not indicated after vaccination. The vaccine is contraindicated in the immunocompromised, persons with anaphylactic allergies to vaccine components, and pregnant women. Varicella vaccine is more temperature sensitive than other vaccines used in the United States. It must be stored frozen at −15° C or colder to retain potency, and it should be discarded if it is not used within 30 minutes of reconstitution.

Side Effects

The most common side effect is soreness at the injection site, which is reported in 25 to 35% of recipients 13 years or older. Varicella-like rashes at the injection site (median of two lesions) have been reported in 3% of recipients in this age group after the first dose and in 1% after the second dose. Nonlocalized rashes with a median of five lesions have been reported in 5.5% of recipients after the first dose and in 0.9% after the second dose. Although the vaccine virus can cause herpes zoster (shingles), the incidence is substantially lower than would be expected after natural varicella (Chapter 383). More severe events occurring in temporal relation to the vaccine have been reported rarely, although a causal relationship has not been established. Transmission of vaccine virus to a contact is extremely rare and appears to take place only with vaccinees in whom a varicella-like rash has developed.

Varicella: Zoster

Clinical trials of a varicella vaccine, approximately 14 times more potent than the varicella vaccine used routinely, among persons 60 years of age or older reported a 51% reduction in the incidence of zoster and a 67% decrease in postherpetic neuralgia. The efficacy against zoster declined with increasing age from 60 to 80 years or older, but there was evidence of continuing

protection against postherpetic neuralgia. The vaccine requires special freezer storage.

Indications

Zoster vaccine is recommended as a single dose for persons 60 years of age or older. Persons with a prior history of zoster may be vaccinated. It is not necessary to elicit a history of varicella or to test for varicella immunity before administration of zoster vaccine. The vaccine is not recommended for immunocompromised persons or pregnant women.

Side Effects

The most common side effect attributed to the vaccine is local reactions.

VACCINES INTENDED PRIMARILY FOR INTERNATIONAL TRAVELERS

Japanese Encephalitis Vaccine

Indications

Japanese encephalitis (Chapter 391) vaccine is indicated primarily for travelers to Asia who will spend a month or longer in endemic areas during the transmission season, especially if travel will include rural areas. In all instances, travelers should be advised to take personal precautions to reduce exposure to mosquito bites. An older vaccine was reported to be 80 to 91% effective in preventing clinical disease. The current whole virus inactivated vaccine (IXIARO, Intercell Biomedical) was licensed based on comparable immunogenicity. The primary series consists of two 0.5-mL doses given intramuscularly on days 0 and 28, with the second dose administered at least 1 week before travel (see Table 17-2). The duration of immunity is unknown. As of 2010, there were no recommendations for booster doses.

Side Effects

Headache and myalgia and local reactions (pain and tenderness) are common, occurring in more than 10% of vaccinees. However, the incidence rates of these events were similar to those in a comparison group, which received PBS and aluminum hydroxide.

Typhoid Vaccine

Indications

Two types of vaccines, a live attenuated Ty21a oral vaccine and a capsular polysaccharide vaccine (ViCPS), appear to be of comparable efficacy (50 to 77%). Typhoid (Chapter 316) vaccine is indicated primarily for travelers to areas where the risk of prolonged exposure to contaminated food and water is high. Because the vaccine is not always effective, food and water precautions are still essential. The vaccine also may be considered for family or other intimate contacts of typhoid carriers and laboratory workers who work with *Salmonella typhi.* For adults and children 6 years and older, either of the vaccines may be used. For Ty21a, one enteric-coated capsule is taken every other day for four doses. Alternatively, a single dose of the ViCPS vaccine may be given. The duration of protection with Ty21a is not known; repetition of the primary series is recommended every 5 years for persons at risk. Boosters are recommended every 2 years for the ViCPS vaccine if persons continue to be at risk. The ViCPS vaccine can be given to children as young as 2 years of age.

Side Effects

Adverse reactions are rare.

Yellow Fever Vaccine

Indications

Yellow fever (Chapter 389) occurs only in areas of South America and Africa. Vaccination with a single dose of the live attenuated 17D strain of virus confers protection to almost all recipients for at least 10 years. A booster dose is recommended every 10 years for persons at continued risk of exposure to yellow fever.

Side Effects

Side effects are uncommon. A rare syndrome of yellow fever vaccine, febrile multiple organ system failure or viscerotropic disease, has been reported, with high rates of mortality, primarily among older adults and persons who have undergone thymectomy or have severe thymic dysfunction being vaccinated for the first time. Yellow fever vaccine should be administered with caution and only after careful counseling to elderly patients who are going to spend time in yellow fever–endemic zones. Yellow fever vaccine should not be given to immunocompromised persons or persons with anaphylactic allergies to eggs. The vaccine is contraindicated in pregnant women on theoretical grounds, although if pregnant women must travel to a high-risk area, they may be vaccinated.

VACCINES FOR POSSIBLE BIOTERRORISM AGENTS

Anthrax Vaccine

Anthrax vaccine adsorbed (AVA) is prepared from a cell-free filtrate of a nonencapsulated strain of anthrax and contains many cell products including protective antigen. Protective antigen is responsible for binding to cells, allowing transport of lethal factor and edema factor into host cells. A recombinant protective antigen (rPA) vaccine is in clinical trials.

Indications

Pre-exposure prophylaxis consists of five doses intramuscularly at 0 and 4 weeks and 6, 12, and 18 months followed by annual boosters. Protective efficacy of an earlier form of the vaccine against cutaneous anthrax was 92.5%. Animal models suggest efficacy against inhalation anthrax. Pre-exposure vaccination is recommended for persons engaged in work involving exposure to high concentrations of *Bacillus anthracis* or in activities with high potential for aerosol production. Vaccine may be given with antibiotics for postexposure prophylaxis (Chapters 20 and 302); the antibiotics should be continued for 7 to 14 days after the third dose of vaccine is given.

Side Effects

The most common adverse events are local reactions, including subcutaneous nodules, which are thought to be due to the deposition of the aluminum-containing adjuvant in subcutaneous tissue.

Smallpox Vaccine

Smallpox vaccine uses vaccinia virus, an orthopox virus that is distinct from variola and cowpox viruses and that provides cross-protection from smallpox. Smallpox vaccine is close to 100% effective when it is administered properly, with a bifurcated needle. Vaccination also prevents or modifies disease when it is administered within 3 to 4 days of exposure and perhaps even after greater delays. The skin usually does not need any special preparation. If alcohol is used for cleaning, the skin should be allowed to dry before vaccination to avoid inactivation of the vaccine. The needle is held perpendicular to the skin; 3 punctures for primary vaccination and 15 punctures for revaccination are made rapidly with enough vigor to ensure that a trace of blood appears within 15 to 20 seconds. With a primary take, the vaccination site should become reddened and pruritic by 3 or 4 days after vaccination; a large vesicle with a red areola forms and becomes pustular by 7 to 11 days. The lesion scabs by the third week. Fever is the most common adverse event. Other more serious complications include eczema vaccinatum, a local or disseminated vaccinia infection in persons with a history of eczema or other exfoliative dermatitis; vaccinia necrosum, which occurs in immunocompromised persons; autoinoculation, especially of the eye, which can cause keratitis and scarring; generalized vaccinia; myopericarditis; and encephalitis. The risk for death from vaccinia has been estimated to be approximately one case per 1 million primary vaccinations.

Indications

The vaccine is indicated for persons who work with orthopox viruses. To increase preparedness for a smallpox attack, vaccination is often recommended for persons who will serve on public health or health care response teams. The duration of immunity is unclear. Revaccination is recommended at least every 10 years for persons who continue to be at risk. Contraindications include history or presence of eczema, other chronic or exfoliative skin conditions, and immunosuppression or pregnancy in the patient or a close household or other contact. Persons who are younger than 1 year, are breastfeeding, or have allergies to vaccine components should not be vaccinated. Because of reports of postvaccination cardiac events, vaccination should be deferred in persons with ischemia or other severe heart diseases or at high risk for ischemic heart disease events (*www.cdc.gov/smallpox*). In the event of exposure to variola, there are no contraindications. Should variola be introduced into a community, vaccination would be indicated for all exposed persons and their close contacts to prevent further spread, and recommendations for more widespread vaccination would have to be evaluated on a case-by-case basis.

Other Agents

Other organisms or products that have been considered potential bioterrorism threats include plague (Chapter 320) and botulinum toxin (Chapter 304). Poisoning with botulinum toxin can be treated with a trivalent antitoxin, available from the Centers for Disease Control and Prevention (see *MMWR*. 2003;52:774; *www.cdc.gov/ncidod/srp/drugs/formulary.html*). An experimental pentavalent botulinum toxoid can be obtained from the Centers for Disease Control and Prevention for laboratory workers at high risk for exposure to toxin. Pre-exposure vaccination is not warranted or feasible for the general population.

OTHER VACCINES

A protein-conjugated vaccine for *Haemophilus influenzae* type b (Hib) may be considered for some adults at high risk for invasive Hib disease (e.g., asplenia, HIV infection).

PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL MEDICINE

MARK R. CULLEN

In the first several decades after World War II, when many American workers came to enjoy coverage by health insurance—for everything but workplace injuries and illnesses—the myth grew that modern work was largely free of the risks of the industrial horrors of past eras. Starting in the 1970s, however, resurgence of societal and medical interest in these consequences of work found that diseases related to work were not truly extinct, just not well observed or studied. Occupational physicians, often cut off from mainstream medical practice, had difficulty changing the perception, and most practicing internists were largely oblivious. It is now recognized that a substantial burden of ill health and disability is due to work-associated physical, chemical, and biologic hazards. Another intriguing possibility, recognized by social epidemiologists, is that work may be injurious to health in ways beyond these tangible risks.

Although tens of thousands of toxic chemicals and other hazards can potentially cause or exacerbate a wide range of acute and chronic conditions, certain basic principles and clinical approaches apply broadly to general and specialty medical practice. This chapter outlines these basics, then briefly summarizes the most common occupational disorders seen by internists in developed countries, and finally reviews the effects of the environmental exposures most likely to be encountered.

PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL DISEASE

It is widely imagined that the major health effects of environmental and occupational exposures are unique disorders best recognized by their failure to fit easily into other diagnostic categories (e.g., arsenic poisoning). In reality, *the major consequences of chemical and physical exposures are, without further exploration of an environmental connection, indistinguishable in clinical presentations from disorders that make up the bulk of outpatient and inpatient medical practice:* rashes, abnormal liver function studies (Chapter 149), wheezing and irritative symptoms of the upper and lower respiratory tract (Chapter 87), various cancers (Chapter 183), peripheral neuropathies (Chapter 428), dysphoria (Chapter 404), and nonspecific cognitive dysfunction (Chapter 409). Although a handful of pathologically distinct disorders still occur, such as silicosis (Chapter 93) and lead poisoning (Chapter 21), when an environmental or workplace agent causes overt disease, physiologic and radiographic studies typically reveal manifestations completely consistent with common diagnoses such as asthma (Chapter 87), contact dermatitis (Chapter 446), fatty liver (Chapter 155), and lung cancer (Chapter 197).

The underlying cause may remain obscure unless the clinician adheres to a disciplined approach designed to investigate and exclude occupational or environmental causes whenever it is appropriate. The best approach is consistent use of the occupational and environmental history, a short series of questions that can be expanded on the basis of the replies (see later). The point is that the internist cannot "wait" to consider occupational or environmental issues until other diseases have been ruled out without running the risk of missing almost every occupational and environmental effect that he or she will encounter.

Whatever the pathway or time course, exposure dose is the major determinant of the risk for development of disease. As in pharmacology (Chapter 28), it is impossible to make any meaningful statement about cause and effect without appreciation of dose. Consider, for example, the difference in health effects among aspirin at 65 mg, 650 mg, and 6500 mg (Chapter 36). Over this two-order magnitude of change, the chemical goes from having one therapeutic target organ to having many and to being potentially lethal. It is no different with lead or organophosphate pesticides or solvents, except that there is rarely as simple a way to determine dose as in the drug situation, where pill bottles are labeled and drug prescriptions are recorded. This limitation is exacerbated because, unlike with drugs, the range of toxic exposures may vary far more widely. For example, water in a contaminated drinking well or poor indoor air in an office could have toxins at a level that is two, three, or even four orders of magnitude (i.e., 10,000 times) lower than the level that may have been evaluated in an epidemiologic study of workers or tested in animals. Fortunately, it is much easier to "range find" than one might presuppose (see later discussion of history), and eagerness for precision—often unattainable—should not interfere with obtaining the great amount of information that *can* be readily gleaned and is often sufficient to act on. The key point is that no attempt to apply clinical information in relation to work or environment can be useful without some effort to characterize exposure dose.

Environmental hazards may affect preferentially vulnerable populations—those with underlying disease, those at the extremes of life, those with atopy, and those with other serious health risks such as smoking or diabetes. Genetic differences may underlie some differences, but few relevant genes have been sufficiently characterized for use in practice. Clinical studies of a host of common occupational diseases have identified behavioral and constitutional cofactors; for example, smoking dramatically increases the risk of lung cancer in asbestos-exposed workers (Chapter 197). This interaction creates a double demand on the clinician—the presence of smoking or atopy in a young woman with cough does not preclude the possibility of an occupational cause of her asthma but rather actually increases the likelihood that such a consideration may be important.

The Occupational and Environmental History and Exposure Assessment

Key to determining whether work and other environmental exposures may be causing or contributing to adverse health is the history. The approach to obtaining this information and to the use of available resources to corroborate and complement it depends on the clinical context. In primary and much

specialty medical care, where it is anticipated that a patient will be observed during a long period into the future, the most important step is to establish the hazards to which the patient may be exposed at work presently, the activities that may have resulted in past harmful exposures potentially relevant to future health (because of latency), and whether the present residential environment, including air and water and food sources, is thought to be contaminated by harmful materials. The recommended approach is to use a simple questionnaire, which can be self-administered or supervised by a medical extender (E-Fig. 18-1). These instruments can then be reviewed together by the patient and physician as time permits and updated over time. When jobs or materials are noted but the actual generic exposures are unknown, the patient and available reference sources can be enlisted to "translate" the history into specifics, such as which metals are being welded or what is actually contained in a cleaning agent or plastic. This information is obligatorily maintained and supplied on request by employers in most developed countries in the form of fact sheets termed *Material Safety Data Sheets*, many of which can be easily found online as well. In this way, the ongoing and former exposures, which may have an impact on health, can be noted and, where important, incorporated into routine preventive care or clinical surveillance for sequelae.

For patients with new clinical complaints or recently diagnosed conditions, the question of an environmental cause looms more urgently, so the approach must be more focused. If symptoms or signs of acute or subacute illness are suggested, the *timing* of recent or unusual environmental exposures in relation to the symptoms is key—more important than specific chemical detail. For example, if the patient develops shortness of breath shortly after the introduction of a new chemical or process at work or after a leak or spill, that fact should drive further questions, such as Did others get sick as well? For recurrent symptoms, such as cough or rash, cyclic changes are most often the strongest clue: Do symptoms get worse on workdays and improve on days off or holidays? For more insidious symptoms, such as weakness or numbness of the extremities or new-onset hepatic dysfunction, the appropriate question would be whether the onset of the abnormality has followed by weeks or months some demonstrable change in the work or home environment. Again, the coincidence of others similarly affected may be more valuable than detailed knowledge of the constituents of that environment. When such a temporal pattern is suggested, further efforts to establish what exposure has actually occurred are warranted, often with specialty consultation when it is available.

In the elucidation of evidently more chronic conditions, such as pulmonary fibrosis, chronic renal insufficiency, or a malignant neoplasm, an alternative approach is suggested because the exposure, if relevant, is usually remote. In this situation, a detailed query about current work or ambient environments is not likely to be helpful in differential diagnosis, although knowledge of a past exposure to an important hazard (such as silica, asbestos, or cadmium) might, on the basis of the knowledge of its effects, influence the sequence of the evaluation. However, it is generally more efficient to explore past exposures *after* the pathophysiologic disturbance has been characterized, focusing inquiry exclusively on factors known to cause or suspected of causing that disorder—as is easily found in suggested texts or literature searches.

In acute or chronic cases, information about *what* the exposure has been (generically) must be augmented by an estimation of exposure dose. A brief exposure to a fume containing a small percentage of lead will not, in general, cause acute lead poisoning (although hosts may differ in their responses), nor will trace contamination of a drinking well with benzene typically cause blood dyscrasias. The patient will rarely be able to supply detailed information about past or even current "dose" but often can provide valuable clues: Did the exposure continue during many years? Were fumes or fibers grossly visible in the air? Were respirators or other protective gear necessary or offered? Have episodes of unprotected exposure ever resulted in irritation or acute discomfort? A positive reply to any of these questions would suggest "high" exposure, where the reference point is the level at which the risk for development of a health effect becomes substantial. Conversely, if exposure has occurred in an otherwise typical office or around a home renovation, the levels of exposure are more likely "low." Nevertheless, such low-level exposure does not exclude a health effect, especially one caused by idiosyncratic mechanisms or occurring in hosts who are more "sensitive" to chemical exposures, a health characteristic found in 2 to 10% of the population. Although not to be condoned because of broader public health consequences, exposures in food and drinking water are uncommon causes of perceptible clinical problems. When concern about the exposure is high, information from patients can be readily supplemented by information from employers (with the patient's consent!) and regulatory or health authorities or by consultation with specialists who should know the levels of most workplace hazards in the community. Finally, with an appropriate understanding of the limits of testing and awareness of "timing" issues in relation to exposure (as with measuring drug levels), an increasing number of hazardous chemicals can be biologically measured in blood or urine. Metals and some pesticides can be reliably tested now, and a broad array of organic chemicals should be amenable for testing in the near future. Random sampling for "unknowns" is rarely helpful and often leads to erroneous conclusions because trace chemicals are ubiquitous.

OCCUPATIONAL AND ENVIRONMENTAL HEALTH DISORDERS COMMON IN PRACTICE

Although almost any medical complaint or condition may have an occupational or environmental cause or contribution, certain conditions encountered in medical practice *commonly* do (Table 18-1). For these conditions, attention to the history is most important and most often rewarding.

Asthma

Men and women with preexisting airways disease tolerate irritants in the workplace poorly and may experience exacerbations in temporal relation to one or more exposures. More important, numerous antigens are extant in the workplace, from large proteins, such as latex and animal danders, to small molecules, such as isocyanates needed to set polyurethane. More than 250 agents have been well characterized, and many others are suspect. Virtually no profession or work is immune. Presentation is often nonspecific; timing of symptoms during or slightly staggered from exposure is the clue to diagnosis. The reward for early recognition of such causes is the likelihood that airway inflammation will abate when the noxious exposure is eliminated; otherwise lifelong, often generalized asthma is the rule (Chapter 87).

Chronic Interstitial and Parenchymal Lung Disorders

The rounded opacities of silicosis (Chapter 93) and coal workers' pneumoconiosis (Chapter 93) radiographically resemble sarcoid (Chapter 95); chronic beryllium disease (Chapter 93), a granulomatous disorder caused by sensitization to this widely used light metal, is clinically identical to sarcoid in almost all respects, but a reasonably specific test for blood and bronchoalveolar lavage fluid is now available to distinguish them. Asbestosis (Chapter 93) in every way is identical to idiopathic pulmonary fibrosis (Chapter 92) except that benign pleural changes often accompany asbestosis, which, unlike idiopathic pulmonary fibrosis, tends to run a far more indolent course and

TABLE 18-1 COMMON OCCUPATIONAL AND ENVIRONMENTAL HEALTH CONDITIONS IN GENERAL PRACTICE

CONDITION	EXPOSURE SETTINGS	COMMENT
Asthma	Virtually any indoor or outdoor workplace	New-onset, recrudescent, or exacerbated asthma
Interstitial and parenchymal lung disorders	Dusts, metals, and organic materials	All parenchymal disorders have one or more environmental causes
Cancers of the respiratory tract	Asbestos, radon, silica, mineral oils, tars, and other carcinogens	Smokers are more likely to be affected
Sensorineural hearing loss	Noise, metals, and solvents	High-frequency loss, especially in younger workers
Musculoskeletal disorders of trunk and limbs	Heavy or stereotyped activities	Cold, vibration, and work stress contribute
Upper airway irritation	Dust and fumes	More common in smokers and atopic persons
Nonspecific building-related illness	Office work	Must exclude *specific* causes
Dermatitis, allergic or irritant	Repeated exposure to unprotected skin	Work and environmental exposures should be considered in every case
Multiple chemical sensitivities	Any	Complication of adverse environmental exposure

usually stops progressing when exposure ceases or within a few years thereafter. Hypersensitivity pneumonitis (Chapter 93) is rarely suspected outside of agricultural settings but is occurring far more often; the causes are likely to be microbial contaminants of work materials, but some chemicals, such as the isocyanates, may also be causal.

Cancers of the Respiratory Tract

Although most carcinomas of the lung and upper airway occur in smokers, occupational exposures to asbestos, silica, and the polyaromatic hydrocarbons in particulate air pollution, diesel exhaust, pitch, and asphalt contribute to the burden, as do radon and carcinogenic metals such as chromium and nickel found in most alloys (Chapter 197). Some organic materials, such as formaldehyde, are also likely culprits. Until there is an established strategy for secondary prevention, patients with these exposures should be observed expectantly; at a minimum, extraordinary efforts should be made to control smoking in these exposed individuals. Asbestos-exposed workers—smokers or otherwise—are additionally at risk for malignant mesothelioma (Chapters 99 and 197), but other than primary prevention, the only clinical implication is awareness for early diagnosis and compassionate care for this still largely incurable industrial disease.

Fatty Liver

With the widespread use of abdominal imaging, fatty liver has been recognized as more common than previously thought (Chapter 155). This disorder is common among individuals exposed regularly to organic solvents, a possibility that should be considered at the same time that infectious, metabolic, and pharmaceutical causes are considered. Once it is suspected, whether or not other factors are also present, exposure should be reduced. Improvement tends to be slow, but the risk of progression is likely to have been averted or at least diminished.

Sensorineural Hearing Loss

Aside from aging, noise is the most important cause of high-frequency sensorineural hearing loss, recognizable as early as in adolescence (Chapter 436). Hobbies such as shooting and loud music may combine with industrial and agricultural noise to accelerate hearing loss. Although it is the responsibility of employers to conduct routine audiograms and to control exposure, clinicians should test noise-exposed patients periodically and reinforce whatever control strategies may be in place at work. Exposure to metals such as lead and organic solvents may compound the risk further.

Musculoskeletal Disorders of the Upper Extremity and Trunk

The most common cause of work disability, including permanent disability, is injury to the back (Chapter 407) and wrist. Repetitive, heavy, awkward, and time-pressured activities are notorious contributors, as are cold and vibration. Although an anatomically localized lesion may be identified and specifically treated in a small fraction of cases, as in carpal tunnel syndrome (Chapter 428) or thoracic outlet obstruction, the most important modalities of care in most cases are early recognition and avoidance of further insult. Physical therapy and medications may hasten recovery but cannot prevent recurrences and even progression unless the causal work and avocational activities are modified.

Upper Airway Irritation

Virtually any smoke, fume, dust, or chemical has potential to irritate the upper respiratory tract (Chapter 93), causing acute or chronic symptoms indistinguishable from common allergic manifestations (Chapter 257) or upper respiratory infections (Chapter 96). Although the mucosae of the eyes, nose, sinuses, and throat tend to be forgiving, recurrent episodes are extremely nettlesome and cause substantial disability. Atopic patients and patients with frequent infections are often the most sensitive to these ubiquitous environmental insults, which must ultimately be addressed along with the symptoms themselves and secondary infections.

Dermatitis

Erythematous rashes are a common consequence of topical exposures to workplace, avocational, and household materials, including latex, plastics, and many foods (Chapter 446). Although the keys to recognition are timing and the anatomic relation to clothing, allergenic and irritating chemicals can find their way into unlikely places, such as the groin and belt lines. Specialty consultation and patch testing are warranted in intractable cases but should not supplant careful observation and history taking in most situations.

Sick Building Syndrome and Nonspecific Building-Related Illness

The effort to reduce the influx of "fresh" air into buildings to save heating and air-conditioning costs has resulted in upper airway and dermal irritation as well as vague central nervous system symptoms such as headache and fatigue, occurring shortly after beginning work and clearing minutes to hours after leaving the affected building. Many occupants are typically affected, especially those who spend the most time in one place. The cause is unknown, but recent evidence suggests that microbial materials may be the most common culprits. In every instance, a search for a specific allergen or irritant is worth undertaking (Chapter 257), but the most remedial sources are poor overall ventilation and dampness in which molds fester. When the cause is remedied, most building occupants typically experience symptomatic improvement. From a clinical perspective, the major consideration is whether any more serious problem, such as asthma, may have also developed.

Multiple Chemical Sensitivities

An environmental illness as transient as a single noxious inhalation or as persistent as a protracted course of nonspecific building-related illness can initiate a cycle of similar symptoms after exposures to odors or irritants at very low levels so that even everyday tasks such as shopping or driving become problematic. A patient typically complains of being "allergic" to everything, although there is no evidence for allergic mechanisms (Chapter 257); the cause of this vexing complication, most prevalent in women, is unknown and may involve psychological as well as physiologic factors. Despite the severity of complaints, which often include fatigue, muscle pain, stridor, chest tightness, and palpitations, laboratory test results are normal. Coexistent anxiety and depression often prompt psychiatric referral (Chapter 404), but the disorder has proved relatively refractory to all treatment modalities. Sympathetic support, environmental modification as needed to provide some symptomatic relief, and candor regarding the unknown nature of the disorder are appropriate; extensive clinical investigations often serve only to reinforce the patient's "sick" role and are best avoided. Despite all efforts, the most severely affected individuals will often seek the care of alternative practitioners (Chapter 38) with compelling if unproven theories and expensive, potentially harmful remedies.

COMMON HAZARDOUS EXPOSURES IN THE WORKPLACE AND AMBIENT ENVIRONMENT

Tens of thousands of chemicals in the workplace, as well as important physical and biologic hazards, may be encountered in the general environment (Table 18-2). Several of these hazards are of major current concern in industrialized countries.

Metals

Exposures to lead and arsenic (Chapter 21), once commonplace in industry, are now generally controlled; concern remains highest for environmental settings, especially for children. There is now greater concern for mercury—entrained in large ocean fish worldwide—and manganese (Chapter 21), a potent neurotoxin in welding fumes and various alloys. For most metals—manganese being a notorious exception—blood or urine tests are available to quantify a patient's burden, but these tests must be mindful of timing, the form of metal, and possible "confounders," such as the largely benign form of arsenic excreted in urine for several days after even a single shellfish meal.

Organic Solvents

These petroleum derivatives remain ubiquitous in workplace and household products. All are irritating, potentially neurotoxic, and, to varying degrees, hepatotoxic (Chapter 110). A few, such as trichloroethylene and *n*-hexane, are more potent but no longer widely used. Benzene and the ethers of ethylene glycol are bone marrow toxins (Chapter 168).

Organohalides

Although these complex organic pesticides and industrial materials are no longer made and sold in developed countries, their remarkable biopersistence has resulted in entrainment into everyone's fat. Worse, the dread byproduct dioxin, once associated with herbicide manufacture, has now been recognized as a predictable consequence of combustion of any chlorine-containing materials. All are suspect carcinogens, although debate remains whether this effect is limited to soft tissue sarcomas (Chapter 209)—a relationship established for dioxin—or promotes cancers more globally.

TABLE 18-2 COMMON HAZARDS IN THE WORKPLACE AND AMBIENT ENVIRONMENT

HAZARD	HEALTH EFFECTS OF GREATEST CONCERN	COMMENTS
Metals	Neurotoxicity, cancer	Most can be measured in blood or urine to assess dose
Organic solvents	Respiratory and dermal irritation, neurotoxicity, hepatotoxicity	Benzene and a few others have unique effects
Organohalides (e.g., DDT, PCBs)	Cancer	Ubiquitous suspect carcinogens of high population concern
Herbicides and pesticides	Rare acute neurotoxicity, unknown long-term effects	Widespread hazards of high population concern
Electromagnetic radiation	Leukemia, glioblastoma	Ubiquitous exposures with unproven effects
Particulate matter	Acute and chronic atherosclerotic cardiovascular disease	Air pollution, workplace
Mold	Allergy	High population concern regarding putative chronic effects
Mineral dusts	Cancer	Old hazards still of high concern (e.g., asbestos, silica)

DDT = dichlorodiphenyltrichloroethane; PCBs = polychlorinated biphenyls.

Herbicides and Pesticides

The acute neurotoxicity and irritant properties of most herbicides and pesticides have been well studied (Chapter 110). These agents are generally well controlled, although both occupational and residential overexposures occasionally occur.

Electromagnetic Radiation

Electric wires, appliances, and, notoriously, cell phones emit low-frequency electromagnetic radiation at levels far below those that cause local thermal injuries (Chapter 19). These radiations are nonionizing, but there is some epidemiologic evidence of an increased risk of childhood leukemia with high-level exposure from household wiring and of excess brain tumors in adult workers with regular exposures. Moreover, recent reports from Europe suggest excess brain cancer in cell phone users. These data are difficult to interpret because study results differ according to how exposure is assessed; the only conclusion is that there is basis for concern and need for further study but not cause for widespread alarm or action other than precaution in the placement of new heavy power lines near schools and residences.

Particulate Matter

Evidence accumulated over the past decade points to the likelihood that ambient air pollution contributes measurably to the risk of cardiovascular disease. Focus has turned from the well-established respiratory irritants—the gases SO_2 and ozone—to the smallest particles, so-called $PM_{2.5}$. These particles are laden with polyaromatic hydrocarbons from diesel exhaust, coal burning, and industrial sources, which are proinflammatory. Unknown yet is whether this risk also accrues to more heavily exposed industrial workers, or those exposed to small particles of other composition, but it appears that controls on air quality have already resulted in reductions both of acute coronary events and overall mortality.

Mold

Molds are ubiquitous and long known for their unpleasant odors and potential for inducing allergic responses (Chapter 257), including asthma. Recently, concern has arisen over the potential for serious effects from various mycotoxins, long problems in veterinary medicine when domestic animals consume contaminated feed; however, a consensus panel concluded that there is no evidence of human risks beyond those well established from living or working in a moldy environment. Mold formation should be prevented wherever possible, especially in schools and offices, where molds contribute to problems with indoor air quality. Identification, with eradication of leaks and other sources of water accumulation, is key.

Mineral Dusts

Although asbestos has been largely abated, silica and human-made mineral fibers remain widely distributed in the environment. Silica (Chapter 93), present in virtually every form of "rock," is a potent cause of lung injury and cancer, so respiratory exposure should be carefully controlled in every setting. The evidence of serious risk from fibrous glass, mineral wool, and other human-made mineral fibers is less clear; probably only the finest fibers, such as slag wool, have cancer-causing potential, but many are potent dermal and upper respiratory irritants and should be well controlled for that reason alone.

SUMMARY

Occupational and environmental health problems remain prevalent, although their spectrum and nature have changed as rapidly as any in medicine and are likely to change even faster as technology, work, and knowledge continue to evolve. Physicians need not necessarily develop a large base of "facts"—themselves subject to revision frequently—but rather an approach that incorporates key elements and provides a foundation for efficient recognition and management of current and future clinical syndromes.

RADIATION INJURY

ARTHUR C. UPTON

The term *radiation injury* denotes any abnormality of form or function caused by electromagnetic waves or accelerated atomic particles. The term is also often applied to the harmful effects of high-intensity ultrasound and electromagnetic fields. The different types of radiation differ markedly in their biologic effects, so each must be dealt with separately in considering the injuries it can cause.

IONIZING RADIATION INJURY

Ionizing radiation occurs as electromagnetic waves of extremely short wavelength (Fig. 19-1) and as accelerated atomic particles (e.g., electrons, protons, neutrons, α particles). The injuries they cause include mutagenic, carcinogenic, and teratogenic effects and various acute and chronic tissue reactions such as erythema, cataract of the lens, sterility, and depression of hematopoiesis.

EPIDEMIOLOGY

Precise data on the frequency of injuries caused by ionizing radiation are not available. Injuries attributable to excessive occupational exposure were prevalent among radiation workers in the era preceding modern safety standards but are seldom encountered in the United States today. The 1986 Chernobyl accident in Ukraine, however, caused radiation sickness in more than 200 emergency workers, injured 28 fatally, released enough radioactivity to require tens of thousands of inhabitants to be evacuated from the surrounding area, and resulted in a collective dose-equivalent commitment of 600,000 person-Sv for the population of the Northern Hemisphere. Less catastrophic but more numerous than reactor accidents are accidents involving medical and industrial γ-ray sources, which are occasionally serious enough to be fatal. Noteworthy in this context is the potential for terrorist attacks in which

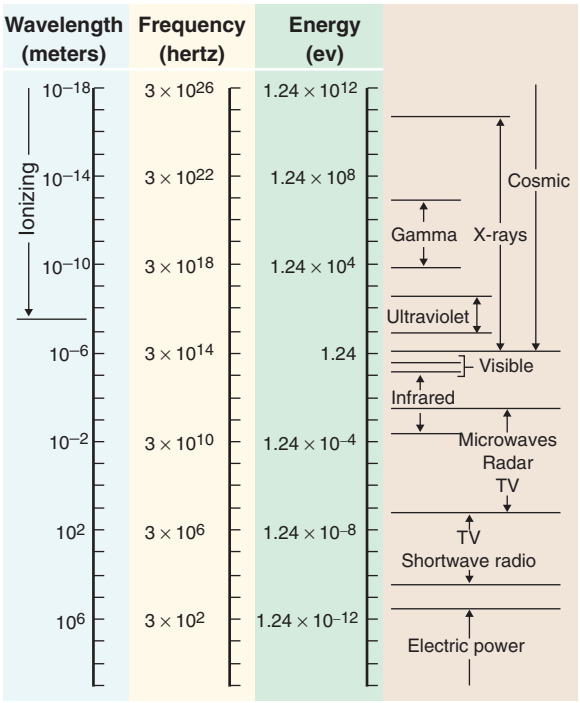

FIGURE 19-1. The electromagnetic spectrum. (From Mettler FA, Upton AC. *Effects of Ionizing Radiation*, 3rd ed. Philadelphia: WB Saunders; 2008.)

nuclear weapons, conventional explosives ("dirty bombs"), or other means may be used to disperse hazardous amounts of radioactivity.

Also of ongoing public health concern is the risk of cancer among the general population from exposure to ionizing radiation. Although no more than 3% of all cancers in the general population are thought to result from natural background ionizing irradiation, a substantially larger percentage of lung cancers are generally attributed to indoor radon. Another concern is the risk of heritable abnormalities resulting from the mutagenic and clastogenic effects of radiation, which have yet to be observed in humans but are well documented in other organisms.

Prenatal irradiation can also cause death, malformations, cataracts, mental retardation, impairment of growth, and behavioral disorders, depending on the dose and the developmental stage of the embryo at the time of exposure. Hence, special precautions are taken to avoid exposure of the embryo to irradiation.

PATHOBIOLOGY

The biologic effects of ionizing radiation result from damage to DNA and other vital molecules by locally deposited energy. Doses of ionizing radiation are therefore measured in terms of energy deposition (Table 19-1).

All humans are exposed continuously to natural background ionizing radiation from (1) cosmic rays; (2) radium and other radioactive elements in the earth's crust; (3) potassium 40, carbon 14, and other radionuclides normally present in human tissues; and (4) inhaled radon and its daughter elements (Table 19-2). In people residing at mile-high elevations, such as Denver, Colorado, the contribution from cosmic rays may be increased twofold; at jet aircraft altitudes, it may be increased more than 100-fold, exceeding 0.005 mSv/hour (1 Sv = 100 rem). Likewise, in regions where the earth's crust is rich in radium, the contribution from this radionuclide may be increased.

Among man-made sources of radiation, the largest is the use of x-rays and other radiographic procedures in medical diagnosis. Smaller amounts of radiation are also received from radioactive minerals in building materials, phosphate fertilizers, and crushed rock; radiation-emitting components of television sets, smoke detectors, and other consumer products; radioactive fallout from atomic weapons; and nuclear power.

Workers in various occupations are exposed to additional doses of ionizing radiation, depending on their job assignments and working conditions. The average annual effective dose received by monitored radiation workers in the United States is less than 1 mSv, and less than 1% of such workers approach the maximal permissible dose limit (50 mSv) in any given year.

TABLE 19-1 IONIZING RADIATION QUANTITIES AND DOSE UNITS

QUANTITY	DOSE UNIT*	DEFINITION
Radioactivity	Becquerel (Bq)	One disintegration per second
Absorbed dose	Gray (Gy)	Energy deposited in tissue (1 J/kg)
Equivalent dose	Sievert (Sv)	Absorbed dose weighted for the quality (potency) of radiation
Effective dose	Sievert (Sv)	Equivalent dose weighted for the sensitivity of exposed organs
Collective effective dose	Person-Sv	Effective dose applied to a population
Committed effective dose	Sievert (Sv)	Effective dose from a given intake of radioactivity to be received during a period extending into the future

*The units of measurement listed are those of the International System, which replaced earlier units such as the rad (1 rad = 0.01 Gy), the rem (1 rem = 0.01 Sv), and the curie (1 Ci = 3.7×10^{10} Bq). Modified from Phillips TL. Radiation injury. In: Wyngaarden JB, Smith LH Jr, Bennett JC, eds. *Cecil Textbook of Medicine*, 19th ed. Philadelphia: WB Saunders; 1992:2351.

Pathogenesis

Ionizing radiation, colliding randomly with atoms and molecules in its path, gives rise to ions and free radicals, which break chemical bonds, cause other molecular alterations, and can ultimately injure the absorbing cell and its neighbors. Any molecule can be altered, but DNA is the critical biologic target because of the limited redundancy of its genetic information. A dose of radiation large enough to kill the average dividing cell (2 Sv) causes hundreds of lesions in its DNA molecules. Most such lesions are reparable, but those produced by a densely ionizing radiation (e.g., proton or α particle) are generally less reparable than those produced by a sparsely ionizing radiation (e.g., x-ray or γ-ray).

Unrepaired or misrepaired damage to DNA may be expressed in the form of mutations, the frequency of which approximates 10^{-5} to 10^{-6} per locus per sievert. Because the mutation rate tends to increase in proportion to the dose, it is inferred that a single ionizing particle traversing a genetic target may suffice to cause a mutation. Radiation damage can also cause changes in chromosome number and structure, the yields of which are characterized

TABLE 19-3 SYMPTOMS, THERAPY, AND PROGNOSIS OF WHOLE BODY IONIZING RADIATION INJURY

	0-1 SV	1-2 SV	2-6 SV	6-10 SV	10-20 SV	>50 SV
Therapeutic needs	None	Observation	Specific treatment	Possible treatment	Palliative	Palliative
Vomiting	None	5-50%	>3 Gy, 100%	100%	100%	100%

Modified from Phillips TL. Radiation injury. In: Wyngaarden JB, Smith LH Jr, Bennett JC, eds. *Cecil Textbook of Medicine*, 19th ed. Philadelphia: WB Saunders; 1992:2354.

well enough so that their frequency in lymphocytes can serve as a biologic dosimeter.

Radiation damage to genes, chromosomes, and other vital organelles may kill cells, especially dividing cells, which are radiosensitive as a class. Measured in terms of proliferative capacity, the survival of dividing cells tends to decrease exponentially with increasing dose; rapid exposure to 1 to 2 Sv generally reduces the surviving population of such cells by about 50%. Except for lymphocytes and oocytes, which tend to die in interphase, most cells killed by irradiation die in mitosis.

Although the killing of cells is a stochastic process, too few cells are killed by a dose less than 0.5 Sv to cause clinically detectable injury in most organs, other than the testis and organs of the embryo. The killing of dividing progenitor cells, if sufficiently extensive, can interfere with the orderly replacement of senescent cells, especially in tissues such as the epidermis, bone marrow, and intestinal epithelium, which are normally characterized by high rates of cell turnover. The timing of the resulting atrophy varies, depending on the cell population dynamics within the tissue in question; in organs such as the liver and vascular endothelium, which are characterized by slow cell turnover, expression of the injury is delayed. Also, if the volume of tissue exposed is small or if the dose is accumulated slowly enough, the effects of irradiation may be counteracted in part by adaptive responses and by compensatory regenerative hyperplasia of surviving cells.

CLINICAL MANIFESTATIONS

Ionizing radiation injuries encompass a diversity of tissue reactions that vary markedly in their dose-response relationships, manifestations, timing, and prognosis. Except for mutagenic and carcinogenic effects, the reactions generally result from the killing of sizable numbers of cells in the exposed tissues and are not detectable unless the dose of radiation exceeds a substantial threshold. For this reason, the reactions are called *nonstochastic* (or *deterministic*) effects. In contrast, the mutagenic and carcinogenic effects of radiation are presumed to have no thresholds and are considered to be *stochastic* in nature. The existing data do not exclude the possibility, however, that the latter effects may have thresholds in the millisievert dose range, and the existence of adaptive responses to radiation (e.g., DNA repair processes) has been interpreted by some observers to support the hypothesis that the net effects of small doses may be beneficial (radiation hormesis).

Tissues in which cells proliferate rapidly are generally the first to exhibit radiation injury. In such tissues, mitotic inhibition and cytologic abnormalities may be detectable immediately after irradiation, whereas ulceration, fibrosis, and other degenerative changes may not appear until months or years later.

Skin

After rapid exposure to a dose of 6 Sv or more, erythema typically appears within 1 day, lasts a few hours, and is followed 2 to 4 weeks later by one or more waves of deeper and more prolonged erythema and epilation. Brief exposure to a dose greater than 10 to 20 Sv may cause transepithelial injury, with moist desquamation, necrosis, and ulceration within 2 to 4 weeks. The ensuing fibrosis of the underlying dermis and vasculature may lead to atrophy and a second wave of ulceration months or years later.

Bone Marrow and Lymphoid Tissue

A dose of 2 to 3 Sv delivered rapidly to the whole body destroys enough lymphocytes to depress the lymphocyte count and immune response within hours. Such a dose also can damage enough hematopoietic cells to cause profound leukopenia and thrombocytopenia within 3 to 5 weeks. If the dose exceeds 5 Sv, fatal infection and hemorrhage are likely to result (Table 19-3).

Intestine

The killing of epithelial stem cells is sufficiently extensive after an acute dose of 10 Sv to cause rapid denudation of the overlying intestinal villi. If the area affected is large, death from a fatal dysentery-like syndrome may ensue within days.

Respiratory Tract

Rapid exposure of the lung to a dose of 6 to 10 Sv damages alveolar cells and the pulmonary vasculature sufficiently to result in acute pneumonitis within 1 to 3 months. If extensive, the process may lead to fatal respiratory failure within 6 months or pulmonary fibrosis and cor pulmonale months or years later.

Gonads

Spermatozoa are relatively radioresistant, but spermatogonia are highly radiosensitive; a dose of 0.15 Sv delivered rapidly to both testes causes oligospermia after a latent period of about 6 weeks, and a dose of 2 to 4 Sv may cause permanent sterility. Oocytes also are radiosensitive; a dose of 1.5 to 2 Sv delivered to both ovaries causes temporary sterility, and a larger dose causes permanent sterility, depending on the woman's age at the time of exposure.

Lens of the Eye

Acute exposure of the lens to more than 0.5 Sv may lead to a microscopic posterior polar opacity within months, and 2 to 3 Sv received in a single brief exposure or 5.5 to 14 Sv accumulated over months may result in a vision-impairing cataract.

Other Tissues and Organs

Other tissues and organs, except in the embryo, are relatively less radiosensitive. All tissues, however, are more radiosensitive when they are rapidly growing.

Whole Body Radiation Injury

Brief exposure of a major part of the body to more than 1 Sv may cause acute radiation syndrome, which is characterized by (1) an initial prodromal stage of malaise, anorexia, nausea, and vomiting; (2) an ensuing latent period; (3) a second (main) phase of illness; and (4) either recovery or death (see Table

19-3). The main phase of the illness usually takes one of four primary forms—hematologic, gastrointestinal, neurovascular, or pulmonary—depending on the size and anatomic distribution of the dose.

Localized or Regional Radiation Injury

In contrast to acute radiation syndrome, the manifestations of which are dramatic and relatively prompt, the reaction to localized irradiation in most tissues tends to evolve more slowly and does not produce symptoms or signs unless the volume of irradiated tissue or the dose is large. Injury produced by a radionuclide follows the anatomic distribution of the radionuclide and its emitted radiation, which may be influenced by the physicochemical state in which the radionuclide is encountered and its portal of entry into the body.

Heritable (Genetic) Effects of Radiation

Radiation-induced heritable mutations and chromosome abnormalities are well documented in other organisms but have yet to be observed in humans. Intensive study of more than 76,000 children of Japanese atomic bomb survivors has failed to detect definite evidence of heritable radiation effects in terms of untoward outcomes of pregnancy, neonatal death, malignant neoplasms, balanced chromosome rearrangements, sex chromosome aneuploidy, alterations in serum or erythrocyte protein phenotypes, changes in gender ratio, or disturbances in growth and development. On the basis of the existing evidence, it is inferred that a dose of at least 1 Sv is required to double the rate of heritable mutations in human germ cells and that, consequently, less than 1% of all genetically determined disease is attributable to natural background irradiation.

Carcinogenic Effects of Radiation

Many but not all types of benign and malignant growths are inducible by irradiation; however, these induced growths characteristically take years or decades to appear and possess no features distinguishing them from growths resulting from other causes. With few exceptions, such growths are detectable only after relatively large doses (>0.5 Sv) and vary in frequency based on the type of neoplasm and the age and gender of the exposed population. Because the existing data are insufficient to describe the dose-incidence relationship precisely or to define how long after irradiation the risk of cancer remains elevated in an exposed population, assessment of the risks of low-level irradiation must be based on models incorporating assumptions about these parameters (Table 19-4). Assessments depend heavily on findings in atomic bomb survivors, whose overall incidence of cancer can be inferred to increase as a linear nonthreshold function of their radiation dose. These estimates cannot be used to predict the risk of cancer attributable to a dose accumulated during weeks, months, or years, however, because experiments with laboratory animals have shown the carcinogenic potency of x-rays or γ-rays to decrease by a factor of 2 to 10 if the exposure is sufficiently prolonged. Furthermore, such estimates represent averages for a nominal population of males and females of all ages, whereas the estimates for breast cancer in women and for thyroid cancer in persons irradiated during childhood are substantially higher than those shown.

TABLE 19-4 ESTIMATED LIFETIME RISK OF VARIOUS CANCERS ATTRIBUTABLE TO 0.1-SV RAPID IRRADIATION

	Excess Cancer Deaths Per 100,000	
TYPE OR SITE OF CANCER	**No.**	**%***

Urinary bladder	25	5
Ovary	24	2
Stomach	22	4
Thyroid	8	16
Other	109	2
Total	613	3

*Percentage increase (rounded off) in the expected risk of death from cancer of that organ in a nonirradiated population.

Modified from National Research Council, National Academy of Sciences. *Health Risks from Exposure to Low Levels of Ionizing Radiation*. BEIR VII, phase 2. Washington, DC: National Academy Press; 2006.

Effects on Lifespan

Mortality from cardiovascular, respiratory, and other non-neoplastic diseases as well as from various forms of cancer is increased in heavily irradiated populations. In lightly irradiated populations, however, these effects are not evident, and survival appears to be enhanced in some instances. This finding has prompted some to infer that the effects of small doses may be beneficial on balance (radiation hormesis), but this hypothesis is highly controversial and has yet to be validated.

Effects of Prenatal Irradiation

The embryo is especially vulnerable to death if it is exposed before implantation; it is susceptible to malformations and other developmental disturbances if it is exposed during subsequent stages of organogenesis, and it is sensitive throughout intrauterine life to the carcinogenic effects of radiation. Among the various disturbances in growth and development, the dose-dependent increase in the frequency of severe mental retardation and the dose-dependent decrease in IQ test scores in atomic bomb survivors who were irradiated between the 8th and 15th weeks and, to a lesser extent, the 16th and 25th weeks after conception are particularly noteworthy.

DIAGNOSIS

Any facility likely to encounter radiation injuries should be able to cope with these injuries and should have personnel on call who are trained and equipped appropriately to do so. At the outset, to evaluate the dose and determine whether the patient has been contaminated with radionuclides, the nature of the exposure and any measurements by film badges or other detectors should be reviewed in detail. If exposure to radionuclides is known or suspected, radioactivity measurements of the whole body, skin, other tissue, blood, urine, and body fluid may be indicated to identify the isotope and evaluate the dose. Malaise, anorexia, nausea, and vomiting suggest a total body dose larger than 1 Sv, as do signs of erythema, hemorrhage, or infection

TREATMENT

In managing radiation injury, good medical judgment and first aid are the priorities. Even a heavily irradiated patient should be evaluated for other types of injury, such as burns, mechanical trauma, and smoke inhalation. If radioactive contamination is known or suspected, rescue and medical personnel who handle the patient should wear gloves and other protective clothing and should take precautions to isolate all contaminated objects.

Apart from symptomatic treatment, management of the hematologic form of acute radiation syndrome is similar to that of pancytopenic leukemia, including reverse isolation, antibiotics to combat infection, granulocyte and platelet transfusions as needed, and intravenous fluids as required to combat dehydration and electrolyte loss (Chapter 189). Colony-stimulating factors and interleukin may be beneficial in patients exposed to 6 to 10 Sv. Bone marrow transplantation (Chapter 181) may be life-saving after a dose of 7 to 10 Sv if a suitably matched donor is available; therefore, specimens of marrow and peripheral blood should be obtained for tissue typing as early as possible.

For localized injuries, treatment depends on the anatomic location and severity. Dry and moist desquamation of the skin, which is the most common injury requiring treatment, is usually managed adequately by simple cleansing. Large or ulcerated lesions should be covered with lanolin and closed dressings that are changed regularly. Severe injuries may require resection of necrotic tissue and skin grafting.

In the event of radioactive contamination, steps should be taken to minimize the uptake and retention of the isotope. Contaminated areas should be rinsed; the mouth, nose, and bronchial tree should be lavaged; and the gastrointestinal tract should be purged, if necessary. Additional measures to inhibit the uptake and retention of specific radionuclides may be indicated. Radioactive iodine may be released during a radiation accident or nuclear detonation and can pose a significant risk of thyroid cancer, especially in children. Stable potassium iodide should be administered to potentially exposed persons (except those who are sensitive to iodine) to inhibit the uptake of radioactive iodine by the thyroid. Its protective effect persists for about 24 hours, and the optimal effect is achieved when potassium iodide is given before exposure or concurrently with exposure. The recommended dose varies, depending on the recipient's age, expected level of thyroid exposure to radioactivity, and pregnancy or lactation status; recommendations range from 130 mg for adults to 16 mg for neonates.

in the skin, conjunctivae, or mucous membranes. The extent of lymphopenia during the first 24 hours varies with the size of the total body dose. Although the granulocyte count may be elevated temporarily during the first 24 to 48 hours, the rapidity with which it and the platelet count fall in the ensuing 2 to 4 weeks also varies with the total body dose. Cytogenetic analysis of cultured lymphocytes for chromosome aberrations can be another useful index of exposure.

PREVENTION

Because the mutagenic and carcinogenic effects of ionizing radiation may have no thresholds, unnecessary exposure should be avoided, and any doses to radiation workers and patients should be kept as low as possible, with particular care taken not to exceed the relevant maximal permissible doses. Facilities using radiation or radiation sources should be designed and equipped appropriately and should provide specialized training and supervision for all workers who may be occupationally exposed. Because indoor radon and computed tomography account for the bulk of the public's exposure to ionizing radiation, measures to limit excessive doses from these sources are warranted.

PROGNOSIS

After a total body dose of 2 Sv or less, survival is probable with little or no treatment; in the 2- to 10-Sv range, appropriate treatment can afford a high rate of survival. If the injury is localized, the prognosis depends on the nature and severity of the reaction. Although recovery is the rule after minor, acute reactions, delayed reactions tend to be irreversible and progressive.

NONIONIZING RADIATION INJURY

Ultraviolet Radiation

The ultraviolet (UV) radiation spectrum (see Fig. 19-1) is subdivided, for convenience, into three bands: UVA, or "black light," 315 to 400 nm; UVB, 280 to 315 nm; and UVC, which is germicidal, 200 to 280 nm. UV radiation does not penetrate deeply into human tissues, so the injuries it causes are confined chiefly to the skin and eyes.

EPIDEMIOLOGY

The largest source of UV radiation for the public is sunlight, which varies in intensity with latitude, elevation, and season. Important man-made sources include sun and tanning lamps, welding arcs, plasma torches, germicidal and black-light lamps, electric arc furnaces, hot-metal operations, mercury-vapor lamps, and some lasers. Low-intensity sources include fluorescent lamps and certain laboratory equipment.

Reactions of the skin to UV radiation, common among fair-skinned people, include sunburn, skin cancer (basal cell and squamous cell carcinoma and, to a lesser extent, melanoma), aging of the skin, solar elastosis, and solar keratosis. Injuries of the eye include photokeratitis, which may result from brief exposure to a high-intensity UV radiation source ("welder's flash") or more prolonged exposure to intense sunlight ("snow blindness"); cortical cataract; and pterygium.

PATHOBIOLOGY

The effects of UV radiation are primarily attributable to its absorption in DNA; pyrimidine dimers are produced and cause mutational changes in exposed cells. Sensitivity to UV radiation may be increased by DNA repair defects (as in xeroderma pigmentosum), by agents (e.g., caffeine) that inhibit repair enzymes, and by photosensitizing agents (e.g., psoralens, sulfonamides, tetracyclines, nalidixic acid, sulfonylureas, thiazides, phenothiazines, furocoumarins, and coal tar) that produce UV radiation–absorbing DNA photoproducts. The carcinogenic action of UV radiation is mediated through direct effects on the exposed cells and depression of local immunity.

CLINICAL MANIFESTATIONS

UVB in sunlight, although far less intense than UVA, plays a more important role in sunburn and skin carcinogenesis, but UVA also contributes to skin carcinogenesis, tanning, some photosensitivity reactions, and aging of the skin.

TREATMENT AND PREVENTION Rx

Excessive exposure to sunlight or other sources of UV radiation should be avoided, especially in fair-skinned individuals. Protective clothing, UV radiation–screening lotions or creams, and UV radiation–blocking sunglasses should be used. To protect occupationally exposed workers, the American Conference of Governmental Industrial Hygienists has recommended 8-hour exposure limits for the unprotected eye that range from 3 mJ/cm^2 to 10^6 mJ/cm^2, depending on the wavelength of the radiation (note that 1 J/second = 1 W). The protective layer of ozone in the stratosphere is being depleted globally by chlorofluorocarbons and other air pollutants, and every 1% decrease in ozone is expected to increase the UV radiation reaching the earth by 1 to 2% and thus increase the rates of nonmelanotic skin cancer by 2 to 6%.

Visible Light

Visible light consists of electromagnetic waves varying in wavelength from 380 nm (violet) to 760 nm (red) (see Fig. 19-1).

PATHOBIOLOGY

Bright, continuously visible light normally elicits an aversion response to protect the eye against injury, so few sources of light other than a laser or the sun during a solar eclipse are large or bright enough to burn the retina under normal viewing conditions.

Photochemical reactions in the retina from sustained exposure to intensities exceeding 0.1 mW/cm^2, such as can result from fixing on a bright source of light, may suffice to produce photochemical blue-light injury. Brief exposure of the retina to intensities exceeding 10 W/cm^2, depending on image size, may cause a retinal burn.

CLINICAL MANIFESTATIONS

Too little illumination can cause eyestrain or seasonal affective disorder, whereas too bright a light can injure the retina (Chapter 431).

TREATMENT AND PREVENTION Rx

Common sense usually suffices to prevent excessive exposure of the retina to light. However, in situations involving potential exposure to high-intensity sources, such as carbon arcs or lasers, appropriate training, proper design of equipment, and protective eye shields are important.

Infrared Radiation

Infrared radiation consists of electromagnetic waves ranging in wavelength from 7×10^{-5} m to 3×10^{-2} m. The injuries caused by infrared radiation are chiefly burns of the skin and cataracts of the lens of the eye.

EPIDEMIOLOGY

Potentially hazardous sources include furnaces, ovens, welding arcs, molten glass, molten metal, and heating lamps. The warning sensation of heat usually prompts aversion in time to prevent burning of the skin by infrared radiation; however, the lens of the eye is vulnerable because it lacks the ability to sense or dissipate heat.

CLINICAL MANIFESTATIONS

Glassblowers, blacksmiths, oven operators, and people working around heating and drying lamps are at increased risk of infrared radiation–induced cataracts (Chapter 431).

TREATMENT AND PREVENTION Rx

Control of infrared radiation hazards requires appropriate shielding of its sources, training of potentially exposed persons, and use of protective clothing and goggles.

Microwave and Radio Frequency Radiation

Microwave and radio frequency radiation consists of electromagnetic waves ranging in frequency from about 3 kHz to 300 GHz.

EPIDEMIOLOGY

Sources of microwave and radio frequency radiation are used widely in radar, televisions, cellular phones, radios, other telecommunications systems,

various industrial operations (e.g., heating, welding, and melting of metals; processing of wood and plastic; high-temperature plasma), household appliances (e.g., microwave ovens), and medical applications (e.g., diathermy and hyperthermia).

PATHOBIOLOGY

The biologic effects of microwave and radio frequency radiation are primarily thermal in nature, but there is growing evidence that some effects may be elicited through nonthermal mechanisms, such as DNA damage, as well. Because of the deep penetration of these types of radiation, the cutaneous burns they cause tend to involve dermal and subcutaneous tissues and to heal slowly.

CLINICAL MANIFESTATIONS

Isolated cases of skin burns, thermal injury to deeper tissues, and death from hyperthermia have been caused by industrial microwave and radio frequency radiation sources. Burns may also result from faulty or improperly used household microwave ovens and from the overexposure of patients with impaired cutaneous pain and temperature senses, which usually warn of impending injury. Other effects reported in the literature but not yet conclusively documented include cataract of the lens, impairment of fertility, developmental disturbances, neurobehavioral abnormalities, depression of immunity, and increased risk for certain cancers. Microwave and radio frequency radiation also can interfere with cardiac pacemakers (Chapter 66) and other medical devices.

TREATMENT AND PREVENTION Rx

Microwave and radio frequency radiation sources must be designed and shielded properly, and potentially exposed persons, especially those with cardiac pacemakers or other sensitive devices, must be trained and supervised properly. In general, detectable heating of tissue requires microwave and radio frequency radiation power densities greater than 10 W/cm^2; avoidance of such exposure, as prescribed by existing federal standards, suffices to prevent such injuries. Further research is needed, however, to address the potential effects of long-term exposure, such as may result from repeated use of mobile phones, especially in children.

Extremely Low Frequency Electromagnetic Fields

Extremely low frequency electromagnetic fields range in frequency from 1 to 3000 Hz, including the 50- to 60-Hz fields associated with alternating currents in electric power distribution systems and appliances. Exposure to such fields is not known to be hazardous, but data suggesting that it may cause reproductive abnormalities and carcinogenic effects have aroused public health concern.

EPIDEMIOLOGY

The earth is surrounded by a naturally occurring electromagnetic field ranging from the low end of the extremely low frequency region to radio frequencies that exist briefly as a result of lightning discharges. Localized electromagnetic fields also are generated by electric power lines, transformers, motors, household appliances, video display tubes, and various medical devices, notably nuclear magnetic resonance imaging systems. These localized fields are generally stronger than naturally existing ones; electromagnetic field flux densities near common household appliances may range up to 270 mG, compared with the average value of 0.6 mG for the earth's magnetic field.

PATHOBIOLOGY

Evaluation of epidemiologic data is complicated by the lack of any known biologic basis for the effects of extremely low frequency electromagnetic fields on tissue, especially because the currents emanating from normal nerve and muscle activity are far stronger than the currents attributable to 1- to 10-mG external 60-Hz fields. Nevertheless, such fields have been reported to influence ion transport, melatonin secretion, and tumor promotion in some model systems.

CLINICAL MANIFESTATIONS

Exceptionally strong fields may affect electrically active tissues (nerves, neuromusculature, heart) and cardiac pacemakers and may raise body temperature. Conflicting epidemiologic studies have evaluated several possibilities: that residential exposure of children to weaker electromagnetic fields may increase their risk of leukemia, that occupational exposure of male utility workers may increase their risk of brain cancer and leukemia, and that chronic exposure of pregnant women to video display tubes may increase their risk of miscarriage and of bearing children with birth defects. None of these links has been established.

TREATMENT AND PREVENTION Rx

Persons with pacemakers should avoid electromagnetic fields stronger than 0.5 mT, which exist around transformers, accelerators, nuclear magnetic resonance imaging systems, and other electrical devices; areas containing such fields should be posted with warning signs. Exposure of workers should be limited in accordance with national guidelines.

Ultrasound

Although frequently classified with nonionizing radiation, ultrasound consists of mechanical vibrations at inaudibly high frequencies (≥16 kHz) and is not a component of the electromagnetic spectrum.

EPIDEMIOLOGY

High-power, low-frequency ultrasound is used widely in science and industry for cleaning, degreasing, plastic welding, liquid extracting, atomizing, homogenizing, and emulsifying operations and in medicine for lithotripsy. Low-power, high-frequency ultrasound is used widely in analytic work and in medical diagnosis (e.g., ultrasonography).

PATHOBIOLOGY

The biologic effects of high-power ultrasound are similar in mechanism to those of mechanical vibration-localized heating, agitation, and fragmentation of tissues.

CLINICAL MANIFESTATIONS

Deleterious effects from prolonged exposure to high-power ultrasound include headache, malaise, tinnitus, vertigo, hypersensitivity to light and sound, and peripheral neuritis. Similar complaints may result from excessive exposure to high-frequency ultrasound through body contact with the source. However, adverse effects have not been shown to result from exposure to high-frequency ultrasound at the low power levels used in medical ultrasonography.

TREATMENT AND PREVENTION Rx

Protection against ultrasound injury requires appropriate isolation and insulation of generating sources and proper training and ear protective devices for persons working around such sources. Yearly audiometric and neurologic examinations of workers are advisable.

BIOTERRORISM

JOHN G. BARTLETT

BIOLOGIC WEAPONS

DEFINITION

Weapons of mass destruction are classified as biologic, chemical, or nuclear. Biologic weapons are microbes or microbial products used for bioterrorism. The potential for mass destruction is evident from a report from the U.S. Office of Technology, which predicted that the release of 100 kg of anthrax spores upwind of Washington, DC, would cause 130,000 to 3 million deaths, matching the lethal potential of a hydrogen bomb. The Centers for Disease Control and Prevention (CDC) is responsible for orchestrating the public health response to a bioterrorism threat or attack in the United States, and the FBI is responsible for the criminal aspects. The CDC has reviewed and classified various potential bioweapons based on public health impact and the properties of such weapons in terms of health consequences, ease of delivery to large populations, potential for civil disruption, and sustainability by person-to-person transmission (Table 20-1). Those with the "best" potential (category A agents) include anthrax, smallpox, plague, botulism, tularemia, and selected viruses that cause viral hemorrhagic fever (Tables 20-1 and 20-2). Of these, the two agents that stand out are anthrax and smallpox.

Despite the enormous potential for mass destruction, the actual application of bioterrorism has been quite limited. During World War II there were major bioweapons programs in the United States, the Soviet Union, Japan, and Germany, but only Japan used its program in any well-established way. The Soviet Union had the largest bioweapons program, with approximately 50 facilities and 60,000 employees. In 1972 the Biologic and Toxin Weapons Convention, which was established to eliminate the threat of bioterrorism, was signed by 140 nations, including the United States and the Soviet Union. The subsequent destiny of the enormous volume of products (e.g., smallpox virus, botulinum toxin, anthrax spores) and most of the highly skilled scientists in this area is largely unknown. Current estimates are that many nations continue to harbor bioweapons programs.

In addition to these large-scale national programs, there is the potential for individuals or dissident groups to use bioweapons. For example, in 1984 a religious cult in Oregon attempted to influence an election by contaminating restaurant salad bars with *Salmonella* to reduce voter turnout; the effort resulted in 751 cases of salmonellosis, but the election was not affected. Aum Shinrykio, a Japanese cult, was responsible for the release of sarin nerve gas, which killed 10 and injured 6000 in Tokyo.

More recently, there were 22 cases of anthrax in the United States during a 2-month period in 2001. Of the 22 cases, 20 were traced directly to six contaminated letters sent to different locations, all with the same molecular type of *Bacillus anthracis*. Some cases were cutaneous because the material in the letters was milled to a relatively large particle size that contaminated surfaces via gravity. By contrast, letters with anthrax that was milled to nearly the size of a single spore resulted in particles that were aerosolized and inhaled, causing inhalational anthrax. During this 2-month period, the CDC assigned 1000 personnel to deal with anthrax issues, prophylactic ciprofloxacin or doxycycline was delivered to 10,000 people who were exposed or possibly exposed, the New York City Health Department fielded more than 15,000 telephone calls, there were hundreds of false threats, and a hospital in Boston was closed for decontamination because of a white powder on the floor that turned out to be from a sugar donut. Ultimately, 11 cases of cutaneous anthrax and 11 of inhalational anthrax were diagnosed. Five of the 11 patients with inhalational anthrax died, despite good medical care. This experience clearly demonstrated the potential impact of a bioterrorism attack on a nation's citizenry.

The next important event was the decision to resume smallpox vaccinations in December 2002. The vaccine was mandatory for military personnel and voluntary for frontline medical personnel who were designated members of smallpox response teams. The concern was that smallpox is an ideal bioterrorism agent because vaccinations had been discontinued and the natural disease was considered to have been eradicated in 1977. The disease is contagious, highly lethal, and largely untreatable. Risk was difficult to assess, although the United States and Russia were the only countries known to have viable smallpox. The restarted vaccine program was hampered by the fact that few contemporary health care personnel knew how to deliver it and that the prior vaccine had been associated with severe complications. Despite these concerns, the experience with about 440,000 military personnel and 36,000

TABLE 20-2 CLINICAL FEATURES OF CATEGORY A AGENTS

	ANTHRAX (INHALATIONAL)	SMALLPOX	PLAGUE (PNEUMONIA)	BOTULISM	VIRAL HEMORRHAGIC FEVER
Cases in U.S. per year	0-1	0	8-10	200-300	0
Clinical features	Flulike, then shock	Fever, then characteristic rash	Pneumonia, hemoptysis	Descending paralysis and involvement of cranial nerves	Hemorrhage and fever
Diagnosis	Blood culture, chest CT	BSL-4 laboratory for virus	Blood and sputum culture	Toxin assay of blood, GI specimens; EMG	BSL-4 laboratory for virus
Mortality	40-50%	30%	10-20%	60%	Variable
Treatment*	Cipro, doxy, or levo + 2nd agent,† 60-100 days	None	Gent/strep (cipro/doxy), 10 days	Antitoxin, ventilator	Ribavirin (some) 7 days
Prevention*	Cipro/doxy	Vaccine	Cipro/doxy	None	None
Infection control	Not transmitted Vaccine	Contact and airborne precautions	Masks	Not transmitted	Contact precautions

*Doses: cipro 400 mg IV q8-12h or 500-750 mg PO bid; levo 500-750 mg IV qd or 500 mg PO qd; doxy 100 mg PO or IV bid; gent 5 mg/kg/day IM or IV; strep 1 g IM bid; ribavirin 16 mg/kg/day IV × 4 days, then 8 mg/kg/day × 3 days or 1000-1200 mg/day PO × 7.
†Imipenem 500 mg IV q6h, rifampin 600 mg IV or PO qd, chloramphenicol 1 g IV q6h, clarithromycin 500 mg PO bid, vancomycin 1 g IV bid, or clindamycin 600 mg IV q8h.
BSL-4 = Biologic Safety Level 4; cipro = ciprofloxacin; CT = computed tomography; doxy = doxycycline; EMG = electromyography; gent = gentamicin; GI = gastrointestinal; levo = levofloxacin; strep = streptomycin; ( ) = alternative to preferred.

civilian medical professionals showed almost none of the previously described serious reactions, but about 50 cases of myocarditis or pericarditis were reported.

More recent planning for bioterrorism has been based on extensive reviews of the anthrax experience of 2001, the 9/11 experience, and two large national simulated bioterrorism attacks: TOPOFF, which was a simulated anthrax attack carried out in Denver in 2000, and Dark Winter, which was a simulated smallpox attack in 2001. The responses have included the Biomedical Advanced Research Development Authority (BARDA), the Project BioShield Act of 2004, and the Pandemic and All-Hazards Preparedness Act of 2006. These initiatives collectively provide extensive resources, organizational structure, and preemptive planning for bioterrorism, but many of these efforts share challenges that are common to pandemics such as influenza and natural disasters such as earthquakes, as well as to bioterrorism. A major concern is surge capacity—the ability of the health system to accommodate a large number of patients in terms of demands for emergency care, medical beds, medical personnel, medications, and equipment such as ventilators.

ANTHRAX

DEFINITION

Infection is caused by *B. anthracis* (Chapter 302). The three recognized forms reflect the portal of entry: inhalation, cutaneous exposure, and ingestion.

EPIDEMIOLOGY

The greatest concern for bioterrorism is the inhaled form of anthrax, which results from the inhalation of *B. anthracis* spores and causes a devastating disease with a mortality rate of about 50%, even with optimal management. The last naturally occurring case of inhalational anthrax in the United States was in 1976. The largest epidemic followed an accidental release of anthrax in Sverdlovsk, Russia, in 1979 and resulted in an estimated 80 to 250 cases. Cutaneous anthrax is the usual naturally occurring zoonotic form. An average of less than 1 case per year now occurs in the United States, with about 2000 naturally occurring cases in the world each year.

PATHOBIOLOGY

When inhalational anthrax is associated with bioterrorism, spores must be milled to less than 5 µm to permit both aerosolization and inhalation. The spores are taken up by alveolar macrophages and migrate to the mediastinal lymph nodes, where they revert to vegetative forms and produce toxins. The protective antigen combines with lethal toxin and edema toxin; these toxins are thought to account for the clinical features.

CLINICAL MANIFESTATIONS

The incubation period is usually 4 to 5 days, but the range is 2 to 43 days after exposure. Inhalational anthrax is a two-stage disease. The initial symptoms are nonspecific and flulike. Features that distinguish this stage from influenza are the lack of coryza and the anticipated exposure history. The second stage is profound sepsis with chest pain, chest compression from large pleural effusions and mediastinal expansion, multiple organ failure, obtundation, cyanosis, hypotension, and death, which may occur within hours. Cutaneous anthrax is characterized by a vesicle that progresses to an eschar associated with substantial surrounding edema, often with regional adenopathy and systemic signs of infection.

DIAGNOSIS

The diagnosis is established by recovery of *B. anthracis* from blood or the infected site. Virtually all patients with inhalational anthrax have positive blood cultures, which frequently turn positive within 12 to 16 hours if cultures were obtained before therapy. Other highly characteristic features of the disease are a chest radiograph that shows a wide mediastinum and a computed tomography scan that shows hyperdense hilar and mediastinal lymph nodes, often with large pleural effusions. A highly characteristic feature of the disease is large, bloody pleural effusions. There may or may not be a pulmonary infiltrate.

TREATMENT

Rx

The most important facets of treatment of inhalational anthrax are supportive care, drainage of pleural effusions, and rapid administration of antibiotics. The drugs approved by the Food and Drug Administration (FDA) for B. anthracis are intravenous penicillin, doxycycline, ciprofloxacin, and levofloxacin (see Table 20-2). In reality, a bioterrorism event involving inhaled anthrax would result in specific recommendations from the CDC. In 2001 the preferred agents were doxycycline or ciprofloxacin combined with a second agent such as penicillin, imipenem, rifampin, chloramphenicol, clarithromycin, vancomycin, or clindamycin, based on sensitivity tests of the epidemic strain. After clinical improvement, the intravenous administration may be changed to oral agents such as ciprofloxacin, levofloxacin, or doxycycline; the total recommended duration of treatment is 60 to 100 days, presumably owing to the persistence of spores. For cutaneous anthrax the recommended treatment is also ciprofloxacin or doxycycline for a total of 60 to 100 days, based on the assumption that a patient with cutaneous anthrax may have inhaled organisms as well.

PREVENTION

In the event of bioterrorism, prophylaxis appears to be critical because the disease is highly lethal, even with antibiotic treatment, and prophylaxis is highly effective. The recommendation for prophylaxis has been oral doxycycline or ciprofloxacin for 60 to 100 days, although more recent animal studies suggest that shorter courses are effective. In fact, anthrax did not develop in any exposed people who received even a single dose of these drugs before the onset of symptoms. An FDA-approved anthrax vaccine administered in six doses to wool sorters and other workers in high-risk occupations is very effective, but other anthrax vaccines appear to be effective with fewer administrations and result in fewer adverse reactions.

PROGNOSIS

Data from the Sverdlovsk outbreak in Russia suggest a mortality rate of 60 to 87%, despite appropriate antibiotics. In the 2001 epidemic in the United States, 5 of 11 patients (45%) with inhalational anthrax died, despite aggressive management. In the fatal cases, the interval between the onset of symptoms and death averaged 3 to 4 days. Survivors had long-term disability.

SMALLPOX

DEFINITION

Smallpox is a systemic infection caused by the virus *Variola major* or *Variola minor* (Chapter 380). The assumption is that any attempt at bioterrorism with smallpox would use *V. major*, which is associated with a substantially higher mortality rate. The virus is viewed as ideal for bioterrorism because it is easy to culture, survives well in aerosols, and is lethal in 30% of cases. Furthermore, most humans are now susceptible because immunization was stopped in the United States and most of the world by 1973.

EPIDEMIOLOGY

The global campaign to eradicate smallpox was initiated in 1966, and the last naturally occurring case was reported in 1977. In 1980 the World Health Organization (WHO) declared smallpox eradicated and recommended that all laboratories destroy their stocks of variola or transfer them to one of two WHO reference laboratories, one in Moscow and the other at the CDC in Atlanta. These remaining isolates were to be destroyed in 1999, but the WHO agreed to retain the supplies in an effort to develop an attenuated vaccine and antiviral drugs. The number of countries that have this virus other than Russia and the United States is not known.

Smallpox is spread from person to person in droplets from the oral pharynx. The greatest risk is to persons within 6 to 8 feet of an infected individual, and prior epidemics have consistently shown that most cases occur in household members and hospital contacts. The secondary attack rate in unvaccinated household members is 37 to 88%. Because the disease has been eradicated, any confirmed case of smallpox implies bioterrorism.

CLINICAL MANIFESTATIONS

The incubation period is usually 12 to 14 days. Initial symptoms are high fever, malaise, prostration, headache, and backache. These symptoms are severe, and most patients are bedridden. The rash usually appears on day 3 as a maculopapular eruption that subsequently evolves through the vesicular and then pustular stages; at 2 to 3 weeks it forms scabs that separate and leave a characteristic pitted scar. The rash begins on the face and forearms and then spreads to the trunk and legs. Pustules have a characteristic firm, round, deep-seated appearance and measure 7 to 10 mm in diameter. Lesions are more dense on the face and extremities, all are in the same stage, and the palms and soles may be involved. An important issue in terms of disease control is that transmission takes place during the rash phase and not during the early pre-rash period of illness.

DIAGNOSIS

Laboratory diagnosis requires fluid collected from a typical vesicular or pustular lesion, preferably by a vaccinated person with appropriate protection. Laboratory testing must be done in a maximum containment facility (Biologic Safety Level 4 [BSL-4] laboratory); tissue culture is used to recover the virus, and polymerase chain reaction and restriction fragment length polymorphism are used to characterize the viral strain. For the clinician, the major issue is the distinction of smallpox from chickenpox or other illnesses characterized by a vesicular rash (Table 20-3). With chickenpox (Chapter 383), the lesions are more superficial, have a centripetal distribution with greater involvement of the trunk and face, and are not all at the same stage of evolution. Patients are also less seriously ill.

Other conditions in the differential diagnosis for a vesicular or pustular rash include disseminated herpes zoster or herpes simplex (Chapter 382), drug eruptions (Chapter 448), erythema multiforme (Chapter 446), enteroviral infection (Chapter 387), secondary syphilis (Chapter 327), monkeypox (Chapter 380), molluscum contagiosum (Chapter 446), and generalized vaccinia. With a generalized maculopapular rash, the differential diagnosis includes measles (Chapter 375), rubella (Chapter 376), drug rash, erythema multiforme, and scarlet fever (Chapter 297).

TABLE 20-3 MAJOR AND MINOR CRITERIA FOR SMALLPOX AND PRIORITY FOR REPORTING TO CENTERS FOR DISEASE CONTROL AND PREVENTION

MAJOR CRITERIA
Fever (>38.3° C) 1-4 days before the onset of rash plus one of the following: headache, prostration, chills, vomiting, abdominal pain
Typical smallpox lesions: firm, round, deep-seated vesicles or pustules with evolution to umbilicated or confluent
Lesions at same stage of development
MINOR CRITERIA
Centrifugal distribution of rash (face and extremities)
First lesions on oral mucosa, palate, face, and arms
Patient appears toxic or moribund
Slow evolution of lesions—each stage lasts at least 1-2 days
Lesions on palms and soles
REPORTING PRIORITY
Report immediately: (1) febrile prodrome, (2) classic smallpox lesions, and (3) lesions in the same stage of development (all 3 present)
Urgent assessment: (1) febrile prodrome and one other major criterion *or* (2) febrile prodrome plus ≥4 minor criteria
Manage as clinically indicated: febrile prodrome and ≥4 minor criteria

TREATMENT Rx

There is no therapy with established merit.

PREVENTION

Vaccination with vaccinia (cowpox) virus before exposure provides significant protection against smallpox. Persons in whom a vesicle or pustule develops or who have a pitted scar at a previous vaccination site have a "take" indicating an immune response. The duration of protection is not well known. Vaccination also provides some protection when given within 4 days after exposure because the immune response to vaccinia is faster than it is to smallpox. The major goal in the event of anticipated bioterrorism is to vaccinate persons with anticipated risks, such as military personnel or hospital-based smallpox response teams. In an outbreak, the highest priority would be first responders, household contacts, and others who have face-to-face contact with patients after the onset of fever.

Vaccination was associated with substantial risk when it was given routinely before 1973. The major currently recognized vaccine-associated complications (Chapter 17) include (1) postvaccinal encephalitis, which is probably an immune reaction; (2) progressive vaccinia, which is a progressive and rapidly lethal complication of disseminated vaccinia seen primarily in patients with defective cell-mediated immunity; (3) generalized vaccinia caused by dissemination of vaccinia; (4) accidental inoculation of other anatomic sites or other persons, usually bedmates; and (5) eczema vaccinatum in patients with a current or past history of eczema or atopic dermatitis. Complications that result from uncontrolled growth of vaccinia can be treated with vaccinia immune globulin. During the recent experience with smallpox vaccination in more than 500,000 U.S. military personnel and health care workers, the frequency of these adverse reactions was modest, and no deaths were recorded. However, another major complication—myopericarditis—was recognized; it was most common with primary vaccination, self-limited, and probably immune mediated.

PLAGUE

DEFINITION

Plague refers to infection by *Yersinia pestis* (Chapter 320).

EPIDEMIOLOGY

Approximately 10 cases of plague occur in the United States annually, but the pneumonic form of disease, which would be anticipated in the event of bioterrorism, is rare, with only about 7 cases in the past 50 years. Thus, any case of pneumonic plague, particularly if acquired in urban areas and outside endemic areas, should arouse suspicion of bioterrorism. An important clinical clue to the diagnosis is severe pneumonia associated with hemoptysis. It is known

TABLE 20-4 VIRAL HEMORRHAGIC FEVERS

AGENT	SOURCE	VECTOR	CLINICAL FEATURES	P-P TX	TREATMENT	MORTALITY (%)
Ebola	Africa	Not known	Fever, rash, DIC	Yes	Supportive	50-90
Marburg	Africa	Not known	Fever, rash	Yes	Supportive	20-70
Lassa fever	Africa	Rodent	Fever, conjunctivitis	Yes	Ribavirin	15-20
New World Arenaviridae	South America	Rodent	GI symptoms, conjunctivitis, adenopathy	Yes	Ribavirin	15-30
Rift Valley fever	Africa, Saudi Arabia	Mosquito	Fever, jaundice, photophobia	No	Ribavirin	<1
Yellow fever	Africa, Americas	Mosquito	Fever, jaundice, conjunctivitis	No	Supportive	20
Omsk hemorrhagic fever	Central Asia	Tick	Fever, cough, conjunctivitis, adenopathy	No	Supportive	1-10
Kyasanur	India	Tick	Biphasic encephalitis	No	Supportive	3-10

DIC = disseminated intravascular coagulation; GI = gastrointestinal; P-P Tx = person-to-person transmission.

that *Y. pestis* was produced in large quantities by Soviet scientists for bioterrorism before this program was abandoned in 1992. The WHO has estimated that a 50-kg release of *Y. pestis* over an urban area of 5 million people would result in 150,000 cases of plague pneumonia and 36,000 deaths.

CLINICAL MANIFESTATIONS

The incubation period is 1 to 6 days. The pneumonic form is associated with bloody sputum, fever, dyspnea, and frequent gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and diarrhea. The course is rapidly progressive, with a sepsis syndrome at 2 to 6 days. Chest radiographs usually show consolidated infiltrates, and about 50% of patients have pleural effusions.

DIAGNOSIS

Y. pestis is a gram-negative coccobacillus that demonstrates bipolar staining and resembles a safety pin. Although the organism may be recognized by Gram stain of sputum, most laboratories require extended periods to identify it with standard methods. If this diagnosis is suspected, the laboratory should be warned so that one culture can be incubated at 28° C for rapid growth and a second at 37° C to permit identification of the capsular antigen. Rapid diagnostic tests are available in some state health departments, the CDC, and some military facilities. The differential diagnosis includes other severe forms of pneumonia or epidemic pneumonia, such as legionnaires' disease (Chapter 322), histoplasmosis (Chapter 340), anthrax (Chapter 302), tularemia (Chapter 319), and influenza (Chapter 372).

TREATMENT

Rx

The preferred drugs are streptomycin or gentamicin; doxycycline and fluoroquinolones such as ciprofloxacin or levofloxacin are alternative agents. The duration of treatment is 10 days.

PREVENTION

Limited data define the efficiency of person-to-person transmission. Current recommendations are for contact and droplet precautions with the use of masks, gowns, gloves, and eye protection. Isolation may be discontinued after 48 hours of antibiotic treatment and clinical improvement. Prophylactic doxycycline or ciprofloxacin is recommended for 7 days for household members, health care workers, and other close contacts of patients. Prophylactic antibiotics are also advocated for other persons with a common-source exposure. As with anthrax, prophylaxis is virtually 100% effective, whereas treatment after the onset of symptoms is much less successful.

PROGNOSIS

The fatality rate of pneumonic plague approaches 100% without therapy. Mortality has been reduced to 5 to 14% with aminoglycoside treatment, but this experience is based largely on syndromes that are generally less severe than plague pneumonia.

BOTULISM

See Chapter 304.

TULAREMIA

See Chapter 319.

VIRAL HEMORRHAGIC FEVER

DEFINITION

The hemorrhagic fever viruses (Chapter 389) include diverse organisms that cause a clinical illness characterized by fever and bleeding. These agents are grouped in four families: Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae (Table 20-4). These viruses are attractive as bioweapons for several reasons: the minimal infecting dose may be as low as 10 virions, they can be distributed by aerosols, mortality rates are virus dependent but often high, they generate great fear, many are transmitted person to person, and no good treatment is available.

EPIDEMIOLOGY

The hemorrhagic fever viruses are not normally found in the United States, Europe, or Australia. They are transmitted by contact with infected animals or arthropod vectors, although the natural reservoir for Ebola and Marburg viruses is not known. Any case of viral hemorrhagic fever in a patient who has not been in an endemic area within the previous 22 days is presumed to represent bioterrorism.

CLINICAL MANIFESTATIONS

The onset of illness is generally nonspecific and consists of fever and myalgias. Additional symptoms are virus dependent (see Table 20-4) and include rash, encephalitis, pharyngitis, adenopathy, and gastrointestinal symptoms. The syndrome progresses to thrombocytopenia with petechiae, hematuria, hematemesis, hemoptysis, and melena. Disseminated intravascular coagulation with shock, delirium, convulsions, and coma may then develop.

DIAGNOSIS

Laboratory features include thrombocytopenia, as well as leukopenia, anemia, or hemoconcentration. All specimens from patients with suspected viral hemorrhagic fever should be referred to the CDC for testing in a BSL-4 laboratory. Personnel in the referring laboratory must be warned, and only designated technicians should be assigned to processing.

TREATMENT

Rx

Ribavirin has activity in vitro against Lassa fever virus, New World arenaviruses, and bunyaviruses, but clinical experience is limited. It is assumed that a limited number of cases involving these viruses would permit the use of intravenous ribavirin, but a mass casualty setting would require oral administration. Treatment of other hemorrhagic fever viruses would largely be limited to supportive care.

PREVENTION

The major concern is nosocomial and household transmission by contact with blood and other body fluids. Patients should be kept in a single-occupant negative-pressure room, and health care personnel should use N95 respirators or powered air-purifying respirators, double gloves, impermeable

gowns, goggles or face shields, and leg and shoe coverings. Nonessential staff and visitors should be excluded. Dedicated medical equipment such as stethoscopes and point-of-care analyzers should be available. Laboratory specimens should not be sent in pneumonic systems, contaminated objects should be cleaned with a 1 : 100 household bleach or similar disinfectant, and contaminated cloth items should be double-bagged and incinerated or autoclaved. Particular care must be exercised in managing corpses.

CHRONIC POISONING: TRACE METALS AND OTHERS

MICHAEL A. MCGUIGAN

DEFINITION

The term *chronic poisoning* refers to toxicity that develops during repeated or continuous exposure to a substance over many months or years. A *trace metal,* which by definition is present in minute quantities, usually refers to metals that are essential to an organism's function; however, this chapter includes a number of metals that are not physiologically required and does not discuss acute poisoning (Chapter 110).

EPIDEMIOLOGY

The source of most of the substances discussed in this chapter is the environment—the home, the workplace, or the outdoors—and most exposures are unintentional. Because many of these metals are essential to normal physiologic functions, another source may be dietary supplements (Chapter 225). The most common site of absorption is the gastrointestinal tract.

The medical literature on chronic low-level exposure is uneven. Although the clinical toxicology of each metal is presented individually, most if not all exposures involve a number of different metals, and the clinical impact of metal-metal interactions is poorly understood.

Lead

EPIDEMIOLOGY

Lead poisoning was recognized more than 2000 years ago. Although lead poisoning is often considered primarily a problem among children of lower socioeconomic status living in dilapidated housing with peeling lead-based paint, lead poisoning also occurs in adults exposed through occupational or nonoccupational activities (Table 21-1). In the United States, approximately 95% of cases of blood lead levels 25 µg/dL or greater in adults are attributed to occupational exposure.

PATHOBIOLOGY

Inhaled fine particulates (<5 µm in diameter) of inorganic lead reach the alveoli and are readily absorbed; larger particles come in contact with airway mucus and are eventually swallowed. Only 20 to 30% of orally ingested lead is absorbed. Organic lead compounds can also be absorbed through the skin. Absorbed lead is distributed first to blood and soft tissue and then to bone, where more than 90% of total body lead is found. Factors contributing to bone demineralization (e.g., prolonged bedrest, pregnancy, menopause) promote the release of lead from bone. Lead is excreted primarily through the kidneys at a rate of about 30 µg/day, which may increase to 200 µg/day with higher body burdens.

TABLE 21-1 COMMON SOURCES OF ADULT LEAD EXPOSURE

OCCUPATIONAL	NONOCCUPATIONAL
Manufacturing Manufacture of storage batteries Secondary smelting Manufacture of primary batteries Primary smelting Welding and cutting operations	Shooting firearms Remodeling or renovation activities Hobbies (e.g., casting, ceramics, stained glass) Retained bullets or gunshot wounds Pica Contaminated food, liquid, or nontraditional medications
Construction Special trade contractors Painting, paperhanging, decorating Lead abatement workers	
Mining Mining of lead and zinc ores	
Wholesale trades Wholesale distribution of electrical apparatus and equipment, wiring supplies, and construction materials	
Retail trades Automobile repair shops	
Transportation, communication, electric, gas, and sanitary services	

TABLE 21-2 SUMMARY OF CLINICAL LEAD TOXICITY

BLOOD LEAD LEVEL (µG/DL)	EFFECTS
<10	Aminolevulinic acid dehydrase inhibition
15–30	Elevation of erythrocyte protoporphyrin
30–39	Mild elevations in blood pressure Altered testicular function
40–49	Increased coproporphyrins and urinary aminolevulinic acid Slowed peripheral nerve conduction
50–59	Reduced hemoglobin synthesis Neurologic symptoms
60–69	Reproductive effects in women
80–90	Anemia Encephalopathic symptoms Nephropathy
100	Encephalopathic signs

CLINICAL MANIFESTATIONS

Lead binds to sulfhydryl groups and adversely affects zinc- and calcium-dependent enzyme systems. This binding interferes with heme synthesis, DNA transcription, and calcium-dependent release of neurotransmitters and of protein kinase C, which regulate cell growth, learning, and memory. In addition, lead affects membrane integrity, steroid metabolism, and vitamin D synthesis in renal tubular cells, and it produces motor axon degeneration and segmental demyelination. The clinical manifestations of lead toxicity are roughly related to the blood lead level (Table 21-2).

Cardiovascular System

A cross-sectional study of 2165 women aged 40 to 59 years found that a change in blood lead levels from the lowest quartile (mean, 1.0 µg/dL; range, 0.5 to 1.6 µg/dL) to the highest quartile (mean, 6.3 µg/dL; range, 4.0 to 31.1 µg/dL) was associated with a significant increase in systolic (by 1.7 mm Hg) and diastolic (by 1.4 mm Hg) blood pressures. At blood lead levels between 10 and 40 µg/dL, lead increases systolic blood pressure by 1 to 2 mm Hg and diastolic pressure by 1.4 mm Hg for every doubling of the

blood lead level. Workers with mean blood lead levels between 40 and 70 µg/dL have an increased risk of death from renal and hypertensive cardiovascular disease. The progression, mechanisms, and effects of therapeutic intervention are unclear in lead-associated hypertension.

Reproductive System

Workplace exposure to lead is associated with decreased fertility, spontaneous abortions, stillbirths, low birthweights, and increased infant mortality. At mean blood levels above 23 µg/dL, lead has a direct toxic effect on spermatogenesis, resulting in decreased sperm counts and abnormal sperm morphology and function.

Renal System

Lead accumulates in proximal tubule cells. Reported clinical findings include Fanconi's syndrome, increased urate excretion, chronic interstitial nephritis, and interference in the renin-aldosterone system. In a population with a mean blood lead level of 8.1 µg/dL, a 10 µg/dL increase in blood lead level was associated with a decrease in creatinine clearance of 10.4 mL/minute.

Nervous System

Chronic encephalopathy is more common than acute encephalopathy (Chapter 422). Early encephalopathic manifestations include changes in cognitive function and mood, early morning sleep disturbance, headache, irritability, lassitude, and loss of libido. Abnormalities in cognition or visual-motor function may be evident on psychometric testing. These findings may occur in workers with blood levels from 18 to 30 µg/dL but are more common in those with levels in the 40- to 60-µg/dL range. The decrease in neuropsychological performance may be comparable to that expected during aging of up to 20 years, although debate continues about the predictability of the effects of blood lead levels below 70 µg/dL. Many of these manifestations respond at least partially to a reduction in the blood lead level.

Lead affects peripheral nerve conduction. Lead-induced peripheral axonal neuropathy (Chapter 428) most commonly involves the motor nerves; it tends to be more severe in the upper extremities and on the dominant side. A subclinical decrease in ulnar nerve motor conduction velocity has been demonstrated at blood lead levels as low as 30 µg/dL. Lead poisoning also predisposes to the development of carpal tunnel and tarsal tunnel syndromes (Chapter 428).

Hematologic System

Lead affects the red cell membrane and interferes with enzymes involved in the synthesis of hemoglobin. The traditional findings in severe poisoning include a hypochromic microcytic anemia and basophilic stippling (Chapter 162).

DIAGNOSIS

The initial steps in the diagnosis of lead poisoning are to identify people involved in high-risk activities (see Table 21-1) and to determine the levels of lead in the venous (not capillary) blood. The diagnosis of lead poisoning should not rely on clinical symptoms and signs because these develop late and generally correlate poorly with blood lead levels. The blood lead level that triggers intervention is not well established for adults, and no national guidelines exist for managing adults with lead poisoning. It is in the best interest of the patient to follow the most conservative standards: a confirmed venous blood lead level of 40 µg/dL or greater should trigger intervention, including improved industrial hygiene, better dust control, and increased ventilation.

TREATMENT

Rx

Treatment is designed to prevent further exposure, to reduce the blood lead level to an acceptable range, and to repair any existing damage. Removal of an individual from a lead environment is recommended if the blood lead level is 50 µg/dL or greater on three tests over 6 months or if a medical condition consistent with lead poisoning has been identified. Removal from the lead source is often associated with a gradual reduction in blood lead levels. Chelation therapy is generally recommended if symptoms or signs are present or if the blood lead level is above 60 µg/dL (Table 21-3).

Calcium disodium ethylenediaminetetraacetic acid ($CaNa_2EDTA$) is the first-line drug for treating asymptomatic adults with high blood lead levels. In the treatment of symptomatic lead poisoning (with or without encephalopathy), $CaNa_2EDTA$ is used in conjunction with dimercaprol (2,3-dimercaptopropanol or BAL). Larger doses of $CaNa_2EDTA$ (50 to 75 mg/kg/day) are used for more severely poisoned patients. A third chelator, succimer (meso-2,3-dimercaptosuccinic acid, DMSA), is approved for the treatment of children with blood lead levels above 45 µg/dL; although succimer has not been approved by the Food and Drug Administration (FDA) for the treatment of adult lead poisoning, adults have been treated successfully with succimer, and it should be considered in place of $CaNa_2EDTA$ monotherapy. D-Penicillamine (3-mercapto-D-valine or penicillamine) is not recommended for the treatment of adult lead poisoning because of the high incidence of adverse drug reactions.

Chelation removes lead from the blood and soft tissues, but little is removed from bone. Redistribution of lead from deep stores after chelation may result in a rebound of blood lead levels and the redevelopment of clinical toxicity. For this reason, individuals should have their blood lead levels measured 2 weeks after the course of chelation has been completed. In general, the clinical response to chelation therapy is variable, and the data demonstrating improved outcomes are not robust. After chelation, if the blood lead level rises into the toxic range or symptoms recur, another course of chelation is indicated, with the same dose and duration used originally.

Mercury

DEFINITION

There are three chemical forms of mercury. Elemental or metallic mercury (Hg^0, quicksilver) is a silver liquid at room temperature. Inorganic mercury occurs in either a mercurous (Hg^+) or a mercuric (Hg^{++}) state. Organic mercurials are attached to short (ethyl or methyl) or long (alkyl or aryl) carbon chains. Each form of mercury can be found in a variety of occupations and products.

EPIDEMIOLOGY

The different chemical forms of mercury enter and are distributed throughout the body via different delivery systems. From a clinical perspective, the most important target organ is the central nervous system, even though the kidney accumulates the most mercury regardless of the chemical type. Chronic poisoning with any of the chemical forms of mercury results in central nervous system toxicity. Ingestion of organic mercury is the most efficient way to get mercury into the brain, followed by the inhalation of elemental mercury vapor; ingestion of inorganic mercury is the least efficient.

PATHOBIOLOGY

Mercury produces toxicity by binding to sulfhydryl groups, thereby inhibiting enzyme systems and disrupting cell membrane integrity. Mercury also binds to amide, amine, carboxyl, and phosphoryl groups. Methyl mercury inhibits choline acetyltransferase, a critical enzyme in the formation of acetylcholine.

Elemental mercury is or has been used in dental amalgams, calibration instruments, electroplating, gold extraction, manometers, and thermometers. Elemental mercury pooled under carpets or floorboards in homes has resulted in clinical toxicity. Chronic parenteral injection of elemental mercury—no longer prescribed medically, but still rarely done by individuals—may produce neurotoxicity. However, ingested elemental mercury is poorly absorbed from the gastrointestinal tract and causes virtually no toxicity. Conversely, nearly 75% of inhaled elemental mercury vapor is absorbed through the lungs. Once it is absorbed, elemental mercury is distributed to the tissues and red blood cells, where it is oxidized to the mercuric form. Some elemental mercury crosses the blood-brain barrier, and oxidation within the central nervous system leads to an accumulation of divalent mercury in the brain because ionized mercury does not readily cross the blood-brain barrier.

Inorganic mercury may be a component of disinfectants, fireworks, preservatives, and photograph developing chemicals. Application of creams or ointments containing inorganic mercury to intact or damaged skin may result in systemic absorption of mercury. Inorganic mercury solutions are corrosive to the gastrointestinal tract, but up to 15% of ingested inorganic mercury is absorbed through the gastrointestinal mucosa. After absorption, the inorganic mercury salt is ionized and penetrates the blood-brain barrier poorly. However, absorbed divalent mercury can be reduced to the metallic form, which does cross the blood-brain barrier.

Organic mercurials are used as pesticides, preservatives, and disinfectants. Coal-fired power plants are a major source of mercury

TABLE 21-3 GENERAL GUIDELINES FOR CHELATION THERAPY

DRUG	ADULT DOSE	INDICATIONS	CONTRAINDICATIONS AND CAUTIONS
Dimercaprol, British antilewisite (BAL)	3–5 mg/kg (75 mg/m^2) IM every 4 hr for 2 days; then every 6 hr for 2 days; then every 12 hr for up to an additional 7 days	Lead: symptomatic poisoning	Administration is by deep intramuscular injections, which are painful Dimercaprol is often administered with $CaNa_2EDTA$ The vehicle is peanut oil—do *not* use intravenously; use is contraindicated in those with peanut allergy
$CaNa_2EDTA$, edetate calcium disodium	20–30 mg/kg/day (1000–1500 mg/m^2/day) as a continuous infusion for 5 days	Lead: symptomatic poisoning or asymptomatic patients with high blood lead levels Manganese: symptomatic patients with blood, serum, or urine manganese levels above reference values	Do *not* use Na_2EDTA $CaNa_2EDTA$ can be given IM in two or three divided doses High doses of $CaNa_2EDTA$ increase zinc excretion and may be toxic to renal glomeruli and proximal tubules
Dimercaptopropanesulfonate (DMPS)	100 mg orally four times/day for 7 days; may repeat therapeutic course after 7 days without therapy if levels are still elevated	Arsenic: symptomatic patients with urine arsenic levels ≥50 μg/L; asymptomatic patients with urine arsenic levels >200 μg/L Manganese: symptomatic patients with blood, serum, or urine manganese levels above reference values Bismuth: symptomatic patients with bismuth blood levels >50 μg/L or urine levels >150 μg/L	
Deferoxamine	6 g as a continuous IV infusion given over 24 hr; may repeat if serum levels are still elevated	Aluminum: symptomatic patients with serum aluminum levels >100 μg/L	
Dimercaptosuccinic acid (DMSA), succimer	10 mg/kg (350 mg/m^2) orally every 8 hr for 5 days; then 10 mg/kg every12 hr for 14 days	Lead: symptomatic poisoning or asymptomatic patients with high blood lead levels Mercury: symptomatic patients with mercury whole blood levels >10 μg/L or 24-hr urine levels ≥20 μg/L	Succimer has a sulfur-like odor

in the environment. Elemental and inorganic mercurials deposited in the environment are bioconverted into organic mercury compounds that are a recognized contaminant of the food chain, particularly in fish. Consumption of fish is the source of nearly all the methyl mercury in the general population. The FDA and the Environmental Protection Agency (EPA) recommend the avoidance of fish with the highest mercury concentrations—king mackerel, shark, swordfish, and tilefish from the Gulf of Mexico. Women of childbearing age and pregnant women should limit their consumption of medium-mercury fish: fresh tuna steak, canned white or albacore tuna, grouper, orange roughy, saltwater trout, bluefish, lobster, halibut, haddock, snapper, and crab. In addition, caution is urged regarding the consumption of fish from local lakes and ponds, which may be more polluted than commercial fish sources.

Organic mercury is highly lipid soluble, well absorbed through the gastrointestinal tract, and widely distributed throughout the body. Organic mercury compounds are metabolized in the body; longer chain mercury compounds are rapidly metabolized to inorganic mercury, whereas short-chain mercury compounds (e.g., methyl mercury) are slowly metabolized to inorganic mercury. Organic mercury readily crosses the blood-brain barrier, and oxidation within the central nervous system leads to the accumulation of mercuric ions in the brain.

CLINICAL MANIFESTATIONS

The chronic inhalation of elemental mercury vapor results in two syndromes. The first syndrome consists of neuropsychiatric manifestations, gingivostomatitis, and tremor. The tremor (Chapter 417) is evident at rest or with motion and may be aggravated with purposeful movement. The second syndrome is erythism, a neuropsychiatric constellation of findings that includes fatigue, insomnia, memory impairment, nervousness, irritability, shyness, social withdrawal, loss of confidence, timidity, and depression.

Chronic occupational exposure to inorganic mercury may cause subclinical psychomotor and neuromuscular abnormalities as well as long-term behavioral impairment. Neuropsychiatric abnormalities (inattention, memory, construction, and motor performance) appear to be dose related (Chapter 409).

Methyl mercury poisoning is cumulative and develops over several years. Based on epidemics of methyl mercury poisoning in Japan and Iraq in which large quantities of organic mercury were consumed, the initial symptoms are fatigue and perioral and extremity paresthesia, followed by difficulty with hand movements and disturbances of vision. The classic picture of methyl mercury poisoning is the gradual onset of ataxia, constricted visual fields, and dysarthria. Other findings are paresthesia, deafness, incoordination, loss of voluntary movement, and mental retardation. The full picture of toxicity is that of psychological, cerebellar, sensory, and motor abnormalities. However, moderate amounts of methyl mercury in the diet have not been linked to adverse effects in adults; most concern relates to potential toxic effects on the fetus and its developing central nervous system.

DIAGNOSIS

The diagnosis of mercury poisoning requires a history of exposure, compatible clinical findings, and elevated mercury levels in blood or urine.

The mean total mercury levels in whole blood and urine in the general population are 1 to 8 μg/L and 4 to 5 μg/L, respectively. Although elevated blood or urine mercury levels are consistent with clinical toxicity, clinical signs or symptoms are poorly correlated with blood or urine mercury levels because of substantial intraindividual and interindividual variation. For example, data in urban adults (mean age, 59 years) showed no significant association between blood mercury levels (mean, 2.1 μg/L; range, 0 to 16 μg/L) and neurobehavioral performance.

A 1 : 1 ratio of red blood cell to plasma mercury suggests inorganic mercury poisoning, whereas a ratio of 10 : 1 suggests organic mercury toxicity. Red blood cell and plasma mercury levels should be requested if the source and type of mercury exposure are unknown. Methyl mercury blood levels of 3 to 5 μg/dL may be found in patients with symptoms. Determination of a methyl mercury level is recommended if the exposure is to a contaminated environmental source.

Arsenic

DEFINITION

Arsenic is a naturally occurring omnipresent element that exists in three valence states: elemental or metallic arsenic (As^0), trivalent (arsenite, As^{3+}), and pentavalent (arsenate, As^{5+}). The trivalent form of arsenic (arsenite) is the most toxic and is responsible for the worldwide public health concern about chronic arsenic poisoning. Organic alkane arsenicals are of low toxicity, and elemental arsenic is virtually nontoxic.

TREATMENT

Rx

Asymptomatic patients with elevated urine mercury levels should have the analyses repeated after a 4-week period without fish consumption.

A patient with mercury poisoning should immediately be removed from the contaminated environment; the source of the mercury must then be identified and removed. Treatment is primarily symptomatic and supportive.

Chelation therapy (see Table 21-3) is used to increase the excretion of mercury, even though improved clinical outcomes have not been demonstrated; increased urinary excretion of mercury alone has become an accepted if empirical clinical goal. There is little agreement on the indications for the initiation or cessation of chelation therapy. The presence of clinical toxicity combined with elevated mercury levels is an accepted indication for chelation therapy, but its role in asymptomatic individuals with mercury levels above background values is controversial. A reasonable end point for chelation is the achievement of background levels of mercury in urine or blood (<20 µg/L or 10 µg/L, respectively). Fish eaters with elevated mercury levels should avoid eating any fish or shellfish for 1 month, after which mercury levels in blood or urine should be reanalyzed. If mercury levels have come down to reference values, low-mercury fish (shrimp, canned light tuna, salmon, pollock, catfish) can be reintroduced into the diet at a frequency of no more than two meals per week.

Succimer (see Table 21-3) is the chelator of choice because it can be given orally and has been effective in reducing brain levels of methyl mercury in animal studies. D-Penicillamine is less effective than succimer and has a higher adverse drug reaction rate. Dimercaprol is not recommended because of its potential to shift mercury from peripheral tissues into the brain. N-acetylcysteine has been proposed as a chelator of methyl mercury, and repeated oral administration may interrupt the enterohepatic recirculation of methyl mercury; however, use of the drug for this purpose has not undergone clinical trials and is not approved by the FDA.

EPIDEMIOLOGY

The major sources of human exposure to arsenic are the environment (mining, seafood, groundwater) and industry (pesticides, pigments, wood preservatives, glass or metal manufacturing, electronics, folk remedies). The arsenic content in the average North American adult diet is less than 1 µg/kg/day. Arsenic in seafood is primarily in the form of organic arsenicals, and the content is variable; freshwater fish may have up to 2 mg/kg, whereas lobster may have up to 22 mg/kg. The EPA drinking water standard is 10 µg/L.

PATHOBIOLOGY

Nearly 90% of ingested or inhaled arsenic is absorbed; little arsenic is absorbed through intact skin. Absorbed arsenic is widely distributed throughout the body, but no form of arsenic readily crosses the blood-brain barrier. Pentavalent arsenic and trivalent arsenic undergo oxidation-reduction reactions, converting one form to the other. Pentavalent arsenic is reduced by glutathione to the more toxic trivalent form. Methylation of trivalent arsenic produces the less toxic monomethylarsenate and dimethylarsenate metabolites, which are excreted in the urine. Organic arsenicals, such as those found in seafood, are essentially nontoxic; they are not metabolized to toxic forms of arsenic and are rapidly excreted in the urine, with an elimination half-life of 4 to 6 hours.

Arsenite (As^{3+}) binds to sulfhydryl groups, resulting in the inhibition of many enzyme systems (glycolysis, pyruvate dehydrogenase, Krebs cycle) and the decreased production of adenosine triphosphate. Arsenate (As^{5+}) replaces phosphate in microsomal enzyme systems, resulting in the uncoupling of oxidative phosphorylation and the decreased production of adenosine triphosphate. Pentavalent arsenate does not bind to sulfhydryl groups. Inorganic arsenic is a human carcinogen.

CLINICAL MANIFESTATIONS

Chronic poisoning develops after the ingestion or inhalation of arsenic over weeks to months, depending on the daily dose. Clinical manifestations develop gradually and are highly variable among exposed individuals. Typical initial manifestations include nonspecific complaints such as a metallic taste in the mouth, anorexia, weight loss, malaise, and weakness.

Skin lesions are some of the most common and earliest nonmalignant toxic effects. Typical dermal findings include melanosis (trunk and extremities), hyperpigmentation (tongue, oral mucosa, axilla), hyperkeratosis (palm, sole), and brittle nails. Less common or late findings include alopecia and white transverse bands (Mees' lines) in the nails (Chapter 450).

Later findings involve the nervous system and carcinogenesis. Neurologic effects are both central and peripheral. Central effects include mild dementia (Chapter 409) and headache; cranial nerves are normal. Peripheral sensory and motor neuropathies (Chapter 428) develop in a stocking-and-glove distribution and cause muscle weakness, muscle atrophy, and ataxia.

Malignant neoplasms include Bowen's disease, basal cell carcinoma, and squamous cell carcinoma (Chapter 210). Lung cancer (Chapter 197) may result from the inhalation of dust containing high levels of arsenic. Arsenic in drinking water has been associated with leukemia, bladder cancer, renal cancer, hepatic cancer, and uterine cancer (Chapter 183). The cancer risk from arsenic in drinking water may be dose related. Studies of populations outside the United States show increases in cancer only when arsenic concentrations in drinking water measure more than several hundred micrograms per liter. Studies of U.S. populations exposed to average drinking water arsenic concentrations of about 190 µg/L have not demonstrated evidence of increased cancer.

Cardiovascular disease includes atherosclerosis, coronary artery disease, and hypertension. Blackfoot disease, peculiar to the southwestern coast of Taiwan, is a form of peripheral vascular disease that results in gangrene of the lower extremities. Other manifestations of exposure to arsenic in drinking water include chronic cough, type 2 diabetes, and reproductive abnormalities such as congenital malformations, miscarriages, and low birthweights.

DIAGNOSIS

The diagnosis of chronic arsenic poisoning depends on an appropriate history of exposure (including a source), compatible clinical manifestations, and documentation of an elevated body burden of arsenic. Principal sources of arsenic are environmental (contaminated water, air, soil) and occupational or industrial. Although seafood may be a source of organic arsenic, it is not associated with clinical toxicity.

Arsenic can be measured in the hair, blood, or urine. Hair analysis is a suboptimal method of determining chronic toxicity. Environmental arsenic is adsorbed to the external surface of the hair and is difficult to remove by washing. Arsenic levels vary within a single hair and among hairs, and there is significant interindividual variability in adsorption of arsenic to hair. Nonetheless, the normal arsenic hair levels are less than 1 µg/g dry weight, and arsenic levels in hair from people with chronic toxicity range from 1 to 5 µg/g or more.

Blood levels of arsenic reflect only very recent exposure and are not reliable indicators of chronic exposure to low levels of arsenic. For example, there is no correlation between blood arsenic levels and drinking water arsenic levels of 6 to 125 µg/L.

Normal urine arsenic levels are less than 50 µg/L or less than 25 µg/24 hours in the absence of seafood consumption. Among people aged 6 years and older in the United States, the 95th percentile for total urinary arsenic is 65.4 µg/L. Urine arsenic levels above 200 µg/L are abnormal. The average urine arsenic level among people with chronic toxicity is 207 µg of

TREATMENT

Rx

Treatment approaches can be stratified according to symptoms and urine levels of inorganic arsenic (Table 21-4). All patients who are symptomatic or who have urine inorganic arsenic levels of 50 µg/L or above should be removed from the source of the arsenic.

Dimercaptopropanesulfonate (DMPS) is the most widely studied chelating agent for chronic arsenic poisoning and is the drug of choice, although it is not approved by the FDA. DMPS forms a water-soluble complex with monomethyl arsenic that is excreted in the urine. In a randomized trial, DMPS therapy (100 mg orally four times/day on alternate weeks for 7 weeks) increased urine arsenic excretion and improved weakness, pigmentation, and lung disease, but it did not improve hematologic and blood chemistry abnormalities, neuropathy, hepatomegaly, keratosis, or skin histology. Chelation should continue until the urine arsenic level is below 50 µg/L. Succimer has not been successful in treating chronic arsenic toxicity, and dimercaprol is not recommended because the lipid-soluble dimercaprol-arsenic complex penetrates the blood-brain barrier. The effectiveness of selenium and vitamin E supplementation in ameliorating arsenic-induced skin changes is controversial.

TABLE 21-4 ARSENIC TREATMENT STRATIFICATION

INORGANIC ARSENIC LEVELS IN URINE (μG/L)	SYMPTOMATIC	ASYMPTOMATIC
<50	Supportive care	No treatment
50–200	Chelation*	Monitor 24-hr urine levels monthly
>200	Chelation*	Chelation*

*Using DMPS (see Table 21-3).

inorganic arsenic per gram of creatinine. Because urine analysis measures total arsenic, elevated levels should be speciated to determine the fractions of inorganic and organic arsenic. If this analysis is not possible, seafood should be eliminated from the patient's diet for 1 week, and the urine analysis repeated.

A nerve conduction study is not a reliable diagnostic tool for chronic arsenic toxicity. Among patients with elevated urine arsenic levels, the results of nerve conduction tests do not correlate well with the presence or absence of clinical neuropathy.

Cadmium

EPIDEMIOLOGY

Cadmium is found as a metal and in a number of industrial chemicals. Cadmium may enter the environment through contamination, fuel combustion, or fertilizer. The majority of cadmium is used occupationally in nickel-cadmium batteries and to protect polyvinyl chloride against heat and light. Cadmium is used as a pigment in coloring the red bags used for infectious hospital waste. When they are incinerated, these bags release cadmium into the environment, so medical waste incinerators are an important environmental source of cadmium. The largest source of most human exposure to cadmium is dietary, with an average daily intake of 10 to 30 μg. Cadmium exposure is doubled in people who smoke tobacco.

PATHOBIOLOGY

Approximately 25% of inhaled cadmium is absorbed. Although normally only 5% of ingested cadmium is absorbed, gastrointestinal absorption is increased in the presence of calcium or iron deficiency or high dietary fat. Cadmium concentrates in the liver and kidneys. Cadmium is poorly excreted from the body; the geometric mean terminal half-life for elimination in creatinine-adjusted urine is estimated to be 19 years. The kidney is the primary target organ in chronic toxicity.

CLINICAL MANIFESTATIONS

The clinical picture of chronic cadmium toxicity is one of irreversible renal toxicity (Chapter 124). Proximal tubule damage results in high urine concentrations of low-molecular-weight proteins, amino acids, glucose, phosphate, and calcium. Decreased glomerular filtration rate and nephrolithiasis may occur. Renal failure is common.

The renal pathophysiologic process may result in calcium deficiency, osteoporosis, osteomalacia, and bone fractures. Other clinical manifestations of chronic cadmium poisoning include male infertility, slowing of visual-motor functioning, and peripheral neuropathies.

The EPA and the International Agency for Research on Cancer have designated cadmium a probable human carcinogen. However, this designation is controversial, and chronic exposure to cadmium may not increase cancer rates. For example, residents of a cadmium-polluted village in England had no increase in cancer rates; a study of residents of a cadmium-polluted area in Belgium found no increase in prostate, kidney, or urinary tract cancers; a retrospective comparison of Japanese residents in high, low, and no cadmium-polluted areas found no differences in cancer mortality; and a study of copper-cadmium alloy workers found no increased risk of lung cancer.

DIAGNOSIS

A tentative diagnosis of chronic cadmium poisoning can be confirmed by measuring elevated urinary cadmium levels (>5 μg/L) and elevated urinary microprotein levels, particularly β_1-microglobulin.

TREATMENT Rx

Treatment of the toxic effects of cadmium is symptomatic and supportive. There is no accepted way to reduce the body burden of cadmium. The use of $CaNa_2EDTA$ or dimercaprol may increase nephrotoxicity. Succimer and N-acetylcysteine have achieved favorable results in animal studies, but neither has been adequately evaluated in human studies.

Manganese

DEFINITION

Manganese is an increasingly important toxin, both environmentally and occupationally. Manganese exists as a metal (metallic manganese, ferromanganese), as inorganic manganese (e.g., chloride or sulfate salts), or as organic manganese.

EPIDEMIOLOGY

Metallic manganese is used in steel production. Inorganic manganese (Mn^{2+}, Mn^{3+}, and Mn^{4+}) is most commonly found in industry and in the environment. Various inorganic manganese compounds are involved in the manufacture of animal feed, batteries, fertilizers, fireworks, fungicides, matches, and potassium permanganate. Organic manganese compounds are used as a fuel oil additive, as fungicides, and as a gasoline additive (methylcyclopentadienyl manganese tricarbonyl [MMT]). Neurotoxicity seen in methcathinone (street name "Cat") abusers has been attributed to manganese.

Manganese is an essential nutrient, acting as a cofactor in enzymatic reactions involving bone mineralization as well as protein and carbohydrate metabolism. As such, it is often a component of parenteral nutrition preparations, and chronic infusion can result in manganese toxicity. Substantial exposure to manganese occurs in people who work in welding, mining, and foundry occupations. People who work with gasoline or as automobile mechanics may be exposed to MMT.

PATHOBIOLOGY

Manganese is absorbed through the gastrointestinal and respiratory tracts and is distributed widely throughout the body. Manganese accumulates in the globus pallidus of the basal ganglia. Bile is the principal route of excretion. The elimination half-life is approximately 40 days, but it is longer for manganese in the central nervous system.

The primary target organ is the central nervous system. Despite the fact that manganese adversely affects enzymes, receptors, and transport systems, the exact mechanisms of toxicity are unclear. A characteristic finding in chronic manganese poisoning is the selective destruction of dopaminergic neurons. The pathophysiologic mechanism is uncertain, but one hypothesis is that Mn^{2+} causes oxidation, the production of free radicals or reactive oxygen species, or the depletion of antioxidants.

CLINICAL MANIFESTATIONS

People who work with manganese may develop a syndrome similar to but not identical with Parkinson's disease (Chapter 416). Findings include an extrapyramidal syndrome (masklike facies, tremor of the extremities at rest or on extension, bradykinesia, stooped posture, shuffling gait, propulsion abnormalities).

Several clinical characteristics may help distinguish between Parkinson's disease and manganese-induced parkinsonism. Manganese-poisoned patients have a "cock walk" and a propensity to fall backward when pushed. These patients often exhibit psychological disturbances early in the disease process. So-called manganese madness includes aggression, irritability, nervousness, and destructive behavior. Uncontrollable spasmodic crying or laughing, singing or dancing, or unfocused running around have been described.

DIAGNOSIS

The initial diagnosis of chronic manganese poisoning relies on a history of exposure and consistent clinical findings. In patients with significant central nervous system findings, T1-weighted magnetic resonance imaging that shows bilateral, symmetrical hyperdensities in the globus pallidus lends strong support to the diagnosis of chronic manganese poisoning.

Positron emission tomography may identify reduced striatal dopamine release.

Manganese levels in body fluids are helpful in establishing a diagnosis. Reference ranges have been established: blood, 40 to 140 µg/L; serum, 1.5 to 26.5 µg/L; and urine, 9.7 to 10.7 µg/L.

TREATMENT Rx

Treatment of chronic manganese toxicity starts with removing the source of the manganese and providing supportive care. The results of chelation with $CaNa_2EDTA$ or DMPS (see Table 21-3) have been equivocal. Although levodopa responsiveness is a hallmark of Parkinson's disease, welders with manganese-induced parkinsonism treated with levodopa showed no improvement over placebo-treated control subjects.

Nickel

EPIDEMIOLOGY

Nickel is absorbed through the lungs, gastrointestinal tract, and skin. Water-soluble nickel compounds (e.g., nickel chloride or sulfate) are absorbed better than insoluble nickel is. Approximately 25% of the nickel in drinking water is absorbed. Nickel applied to the skin is absorbed into the skin but may not reach the circulation. The urine is the primary means of excretion of nickel from the body.

PATHOBIOLOGY

Nickel is used in a large number of metal alloys and in batteries, electroplating (e.g., table cutlery and some jewelry), coins, surgical staples, and some joint prostheses. Nickel is also present in drinking water; the EPA standard is 0.02 mg/kg/day.

Nickel appears to be an essential element in the body, but its physiologic role is unclear. Nickel crosses the cell membrane through calcium channels and competes with calcium for some receptors.

CLINICAL MANIFESTATIONS

Contact dermatitis (Chapter 446) is the most common manifestation of nickel toxicity. Exposure to consumer products containing nickel, particularly jewelry, causes sensitization and contact dermatitis in as many as 30% of people. Once sensitization has occurred, the severity of subsequent reactions is related to the dose of nickel.

Chronic occupational exposure to nickel dust and fumes has been associated with respiratory tract disease, including nasal, laryngeal, and lung cancers (Chapter 183). The EPA has identified nickel dust and nickel subsulfide as class A human carcinogens. Exposure to nickel in nonindustrial settings, such as ingestion of nickel in water or food or dermal contact, has not been associated with an increased risk of cancer.

DIAGNOSIS

Nickel levels in blood or urine are not useful in establishing either excessive exposure or risk of disease.

TREATMENT Rx

There is no specific treatment of nickel-induced dermal sensitivity.

OTHER TOXIC METALS

Aluminum

EPIDEMIOLOGY

Aluminum is the most abundant metal. It is widely available in consumer products such as food, water, cookware, food wraps, cans, antiperspirants, medications (especially antacids and phosphate binders), and dialysate fluids. North Americans consume 7 to 9 mg of aluminum in their diets each day. Industrial exposure to aluminum may result in significant toxicity.

PATHOBIOLOGY

Gastrointestinal tract absorption of aluminum ranges from 0.1 to 1%. Once it is absorbed, aluminum is bound to transferrin and distributed throughout the body, concentrating in bone and lung. The kidneys are the primary route of aluminum excretion, and a compromised ability to excrete aluminum is an important factor in the development of aluminum toxicity outside of the occupational setting. Rare individuals may accumulate significant amounts of aluminum from antiperspirants.

Aluminum blocks the incorporation of calcium into bones and inhibits osteoblastic and osteoclastic activity. In patients with renal failure, aluminum has been identified as a potential contributor to anemia, dialysis encephalopathy, and renal osteodystrophy.

CLINICAL MANIFESTATIONS

The central nervous system is a target organ for aluminum toxicity. The findings in dialysis encephalopathy (Chapters 132 and 133), which develops over months, include stuttering or stammering speech, directional disorientation, personality changes, myoclonus, motor apraxia, convulsions, and hallucinations. Industrial aluminum workers have developed cognitive defects, depression, incoordination, poor memory, and tremor. The relationship between aluminum exposure and Alzheimer's disease is controversial.

Chronic exposure to excessive aluminum may cause osteomalacia (Chapter 252), spontaneous fractures, and bone pain. Hypochromic, microcytic anemia (Chapter 162) that is unresponsive to iron therapy correlates with aluminum levels in the plasma or erythrocytes. Aluminum workers have an increased risk for the development of lung or bladder cancer (Chapter 203).

DIAGNOSIS

The background serum aluminum levels in normal individuals are less than 10 µg/L. Patients undergoing chronic dialysis may have serum aluminum levels up to 50 µg/L. Levels above 60 µg/L indicate increased absorption, serum levels above 100 µg/L are potentially toxic, and serum levels above 200 µg/L are usually associated with clinical symptoms and signs of toxicity.

TREATMENT Rx

Elevated serum aluminum levels can be brought down with extracorporeal clearance techniques, such as hemodialysis and hemofiltration. Deferoxamine (see Table 21-3) is indicated when serum aluminum levels exceed 100 µg/L. In hemodialysis patients, 2.5 mg/kg/week is as effective as the standard dose of deferoxamine (5 mg/kg/week) for treating aluminum overload.■

Beryllium

EPIDEMIOLOGY

Beryllium occurs naturally in rocks, coal, oil, soil, and volcanic dust. Commercially, beryllium is used in metal alloys for aerospace, aircraft, sports equipment (golf clubs, bicycle frames), and automotive manufacturing; in electronics and computers; in ceramics; and in defense weapons. Beryllium is naturally present in tobacco and may be inhaled during smoking.

PATHOBIOLOGY

Inhaled beryllium is cleared from the respiratory tract by mucociliary action and alveolar macrophages. Once it is absorbed, beryllium is distributed to the bones, liver, kidneys, lung parenchyma, and lymphatic system. The kidney is the primary route of beryllium excretion.

Repeated exposure to beryllium causes a cell-mediated immune response involving T lymphocytes and the release of T_H1 cytokines in genetically susceptible persons (Chapter 93). The cell-mediated response is persistent and results in the accumulation of immune effector cells (sensitized T lymphocytes, macrophages) that form granulomas and mononuclear cell infiltrations. A genetic predisposition to the development of chronic beryllium disease has been postulated. Dermal exposure to beryllium may cause irritative or atopic dermatitis as well as beryllium-containing foreign bodies and granulomas. The EPA considers beryllium to be a probable human carcinogen.

CLINICAL MANIFESTATIONS

Chronic beryllium disease is a progressive systemic hypersensitivity disease affecting the lungs and lymphatic system (Chapter 93). Clinical effects

include progressive dyspnea, chest pain, weight loss, fatigue, anorexia, and fevers. Skin lesions, lymphadenopathy, and hepatosplenomegaly may occur. The pulmonary disease is progressive and may lead to respiratory failure within several years.

On pulmonary function testing, one third of patients have a predominantly obstructive pattern; one fourth have a predominantly restrictive pattern; one third have a reduced carbon monoxide diffusion capacity, with normal airflow and lung volumes; and some have a mix of obstruction and restriction (Chapter 85). A chest radiograph is normal early in the course, but later it shows diffuse bilateral infiltrates and hilar lymphadenopathy. Beryllium sensitivity is confirmed by the blood beryllium lymphocyte proliferation test. Tissue for histologic analysis from transbronchial or open lung biopsy may confirm the diagnosis.

TREATMENT Rx

Treatment involves removing the patient from exposure to beryllium, slowing or halting the progression of the disease with corticosteroids, and providing symptomatic and supportive care.

Bismuth

EPIDEMIOLOGY

Bismuth has been used in the treatment of gastrointestinal disorders such as ulcers, diarrhea, and *Helicobacter pylori* infection. Two forms of bismuth are toxic; lipid-soluble organic compounds (e.g., bismuth subgallate) are neurotoxic, and some water-soluble organic compounds (e.g., bismuth triglycollamate) are nephrotoxic.

PATHOBIOLOGY

Parenterally administered bismuth is distributed throughout the body but concentrates in the kidneys and liver. Elimination is through the kidneys, with a terminal elimination half-life of 3 to 10 weeks.

In the blood, bismuth binds to macroglobulins, immunoglobulins, lipoproteins, and haptoglobin. In the kidney, bismuth concentrates in the proximal tubule and causes necrosis. The mechanism of the neurologic effects is unclear.

CLINICAL MANIFESTATIONS

Chronic exposure to bismuth causes gastrointestinal, dermatologic, renal, and neurologic effects. Gastrointestinal effects include increased salivation, discoloration of the oral mucosa and gums, ulcerative stomatitis, nausea and vomiting, and diarrhea. Dermatologic effects are primarily a generalized rash after parenteral administration. Renal effects include nephritis, tubular necrosis, and renal failure.

The primary neurologic effect is an encephalopathy that develops in two distinct phases. The prodrome lasts up to several months and consists of asthenia, somnolence, depression, anxiety, and sometimes hallucinations. This prodrome is followed by the rapid onset (1 to 2 days) of encephalopathy characterized by confusion progressing to coma or dementia, dysarthria, disturbances of walking and standing, and tremor with myoclonic jerks. Chronic bismuth poisoning is associated with a distinctive electroencephalographic pattern: bilateral low-voltage diffuse beta frequencies that are maximal in the frontal and central regions and accentuated during hyperventilation.

The diagnosis of chronic bismuth toxicity is based on a history of exposure and a consistent clinical picture. Blood and urine levels of bismuth may be helpful. In chronic toxicity, the blood bismuth level is 50 to 1600 μg/L, and the urine level is 150 to 1250 μg/L. The median blood bismuth levels in patients with bismuth encephalopathy are in the range of 680 to 700 μg/L. In patients taking a bismuth product therapeutically, a blood bismuth level above 50 μg/L is a concern; a blood bismuth level above 100 μg/L is an indication to discontinue bismuth therapy.

TREATMENT Rx

Treatment of bismuth toxicity starts with stopping exposure to bismuth. DMPS administration (see Table 21-3) results in increased renal excretion of bismuth, but such therapy has not been shown to improve clinical outcomes.

Chromium

The most common forms of chromium in the environment are metallic chromium, trivalent chromium, and hexavalent chromium. Hexavalent chromium is the most toxic form. Trivalent chromium is essential for normal glucose tolerance; chromium picolinate is an alternative dietary supplement.

The trivalent and hexavalent chromiums are the most commonly used forms in industry. Chronic chromium toxicity is essentially an occupational disease related to tanning, metal alloys and electroplating (including surgical metals), photography, dyes, and cement.

Hexavalent chromium is absorbed primarily through the respiratory tract, with substantially smaller amounts absorbed through the gastrointestinal tract. The other valences are poorly absorbed. Hexavalent chromium is a skin and mucous membrane irritant. In dichromate compounds, hexavalent chromium binds to cellular and nuclear proteins and accumulates in red blood cells and platelets. Reduction of hexavalent to trivalent chromium creates intermediates that cause oxidative damage to DNA. Hexavalent chromium is a human carcinogen (lung cancer), but chromium and trivalent chromium are not classifiable. The EPA standard for chromium in drinking water is 100 μg/L.

Chronic occupational exposure to high levels of airborne hexavalent chromium has been associated with upper airway irritation (including nasal septum ulceration), bronchospasm, and an increased incidence of lung cancer. Repeated exposure to dichromate dust causes conjunctivitis and lacrimation. Dermal effects include irritation and chronic full-thickness ulcers. Chronic ingestion of high doses of chromium picolinate may cause renal impairment. The chronic drinking of water contaminated with hexavalent chromium may be associated with the development of stomach cancer. Reference levels of serum chromium are 0.05 to 0.16 μg/L. Treatment of chromium toxicity is symptomatic and supportive.

Cobalt

Cobalt is a naturally occurring element that exists as a metal, as a stable isotope, and as radioactive isotopes. The general public is rarely exposed to the radioactive isotopes (^{60}Co is used in radiation therapy). The metal is found in paints, enamels, and alloys used for household appliances, cutting tools, and joint replacements and surgical implants. Cobalt is a normal part of vitamin B_{12}. The average daily North American diet contains 5 to 40 μg of cobalt. Cobalt is absorbed through the gastrointestinal and respiratory tracts, distributed throughout the body, and excreted in the urine. Inhalation of cobalt is associated with obstructive and interstitial pulmonary disease. The interstitial pneumonitis is a fibrosing alveolitis, with leukocyte and multinucleated giant cell infiltration (Chapter 92). The process may be an immunoglobulin E–mediated response to cobalt reactivity. Chronic ingestion of or industrial exposure to cobalt produces a cardiomyopathy with pericardial effusions and biventricular heart failure (beer drinkers' cardiomyopathy of the 1960s). Cobalt levels are not useful in the diagnosis or management of chronic cobalt poisoning. The diagnosis is based on a history of exposure and compatible pulmonary findings. Medical evaluation should use standard methods for assessing pulmonary and cardiac function. Treatment consists of removing the patient from the source of cobalt and symptomatic and supportive care; both *N*-acetylcysteine and $CaNa_2EDTA$ have been used, but there is no definitive clinical evidence of benefit.

Selenium

Selenium is used in the vulcanization of rubber, the manufacture of some red glass, the electronics and semiconductor industries, and some pharmaceutical products and dandruff shampoos. Selenium is absorbed through the gastrointestinal and respiratory tracts and accumulates primarily in the liver and kidneys. Selenium is cleared from the body in the urine and feces. The mechanism of toxicity is not clear, but one hypothesis is that selenium inhibits sulfhydryl enzymes, resulting in a reduction in intracellular oxidative reactions.

Chronic exposure to selenium compounds in animals results in hepatotoxicity and decreased growth. In humans, dermal effects include alopecia, abnormal nail formation, and discoloration and decay of the teeth. Chronic high-dose dietary selenium can cause neurologic effects such as paresthesia and paresis. Elevated selenium levels in body fluids have been associated with clinical toxicity. The diagnosis of selenium toxicity relies on identification of a source, compatible clinical findings, and elevated whole blood selenium levels. Whole blood selenium levels vary with dietary intake; people with a normal selenium intake (90 to 168 μg/day) have levels ranging from 0.143 to 0.211 μg/L. Treatment of chronic selenium toxicity consists of removing

FIGURE 21-1. Fifty-six-year-old woman (left) who has had discolored skin since age 14 years. At age 11 the patient was given nose drops of unknown composition for "allergies," and 3 years later her skin turned gray. She has argyria; a skin biopsy confirmed silver deposition. A person with normal-colored skin (right) is shown for comparison. (From Bouts BA. Images in clinical medicine: Argyria. *N Engl J Med*. 1999;340:1554).

the patient from the selenium source and providing symptomatic and supportive care. Chelating agents are not useful.

Silver

Silver is used widely in photography, electronics, electrical equipment, metal alloys, and antibacterial agents. Silver is ingested in water and foods. Silver toxicity develops after the ingestion of at least 25 g of silver over 6 months.

Silver is absorbed through the gastrointestinal tract, lungs, and skin. Ingested silver undergoes a significant hepatic first-pass effect. Silver has a high affinity for sulfhydryl groups and other proteins. Inorganic silver salts precipitate intracellularly and in turn are complexed with DNA, RNA, and other proteins; alternatively, ascorbic acid or catecholamines can reduce silver salts to the metallic form. Silver is not carcinogenic. Silver is eliminated primarily in the feces; little is excreted in the urine.

The dermal picture of chronic silver poisoning is argyria, an irreversible blue-gray pigmentation of the skin (Fig. 21-1). In the kidneys, silver is deposited in the basement membrane of the glomerulus; altered renal function would be expected but has not been documented clinically. Silver levels in body fluids have not been useful in establishing the diagnosis of chronic silver intoxication. Diagnosis is based on a history of exposure and a compatible clinical picture. Reference levels of serum silver are less than 0.5 μg/L. Treatment of chronic silver intoxication consists of removing the patient from the silver source and providing symptomatic and supportive care. Chelating agents are not useful.

Uranium

Uranium causes toxicity because of its chemical effects or its radiation effects (Chapter 19). Uranium compounds are used in photography and as dyes or fixatives; depleted uranium is used in military equipment. Uranium is poorly absorbed from all exposed sites. Two percent of the uranium in drinking water and food is absorbed into the body. Two thirds of the uranium in the body is in the bones, and about 15% is in the liver.

Uranium decays into radium and then into radon, a radioactive gas that seeps into building foundations in particular geographic areas. Although radon is a respiratory carcinogen (Chapter 197), uranium itself is not carcinogenic. The chemical toxicity of uranium affects the kidneys and lungs. Uranium is nephrotoxic but has not led to increased mortality from renal disease in uranium workers. The injury to the lungs involves nonmalignant damage to alveolar type II cells, but it does not increase mortality from respiratory disease in uranium workers. Treatment of uranium toxicity consists of removing the patient from the uranium source and providing symptomatic and supportive care. Chelators are not recommended.

Although alkalinization of the urine with sodium bicarbonate enhances removal of the uranium molecule from the body, no interventions reduce the effects of chronic uranium toxicity.

Zinc

Zinc is a common element found in air, soil, water, and food. It is widely used in metal alloys, cosmetics, and medications and as an alternative dietary supplement. The oral bioavailability of zinc is variable and depends on the formulation and amount ingested. After ingestion, zinc is concentrated in the liver before being distributed throughout the body. Muscle and bone contain 90% of the total body burden of zinc. High levels of zinc stimulate the synthesis of metallothionein in the liver and in the gastrointestinal mucosal cells. Zinc is eliminated from the body primarily through the gastrointestinal tract. Chronic ingestion of zinc in doses as low as 2 mg/kg/day may lead to microcytic anemia secondary to zinc-induced copper deficiency (a result of increased gastrointestinal mucosal cell metallothionein). Chronic ingestion of high doses of zinc causes nausea, vomiting, and abdominal cramping; variable increases in low-density lipoprotein levels and decreases in high-density lipoprotein levels; and impaired white blood cell function. Treatment of chronic zinc toxicity consists of removing the patient from the zinc source and providing symptomatic and supportive care. The use of chelating agents is not recommended.

EPIDEMIOLOGY OF AGING: IMPLICATIONS OF THE AGING OF SOCIETY

LINDA P. FRIED

DEMOGRAPHIC REVOLUTION: TRANSITION TO AN AGING SOCIETY

There are now more than 39 million persons 65 years and older in the United States, or more than 12% of the population; in contrast, in 1900, there were 3 million persons 65 years and older, or just 4% of the population. By 2030, about 20% of the U.S. population will be older than 65. By 2050, the current population of older adults will more than double. These increases result from dramatic increases in life expectancy over the past century: in 1900, at birth, men could expect to live to 48 years, and women could expect to live to 51 years on average; by 2008, life expectancy had increased to 75 and 81 years, respectively. Substantial years are now lived after the age of 65 by a large proportion of the population.

With this significant demographic shift, older adults have become a large proportion of all persons with each of the major chronic diseases (Table 22-1). As a result of this burden of disease, people 65 years and older account for about 27% of U.S. health care expenditures, although they represent less than 13% of the U.S. population. Older adults make, on average, 11 outpatient visits per year. People age 75 years and older make almost twice as many emergency department visits as people of all younger ages combined.

HEALTH OF OLDER ADULTS

Changes in Health Status of Older Adults

By many measures, overall well-being is improving for the current generation of older adults compared with previous birth cohorts. In 2007, 39% of persons 65 years and older reported being in excellent or very good health. Educational status, a strong predictor of health behavior and health outcomes, is increasing. In 1950, 17.7% of persons 65 years and older had a high school diploma or higher, and 3.6% had a bachelor's degree or higher; by 2007, these percentages had increased to 74% and 19%. Physical disability, which is an adverse outcome of chronic diseases and aging, is reported by 37% of older adults; however, the remaining 63% are not disabled, and disability rates appear to have declined in the past 10 years.

In 1900, pneumonia and influenza, tuberculosis, diarrhea, and enteritis were the leading causes of death and accounted for 30% of all deaths in persons older than 65 years. Now, heart disease is the leading cause of death in persons 65 and older, followed by cancer, stroke, chronic lower respiratory diseases, Alzheimer's disease, diabetes mellitus, pneumonia, and influenza; the first three diseases accounted for nearly 60% of all deaths. Among persons 85 years and older, heart disease alone is responsible for about 35% of all deaths. Alzheimer's disease is the fourth leading cause of death in women 85 years and older, but it is a less common cause in men.

Death rates for people 65 years and older have declined substantially in the past three decades for heart disease, stroke, pneumonia, and influenza. The first two of these declines are due to a combination of improved medical care, risk factor reductions, and health-promoting changes in lifestyle. Conversely, mortality from chronic obstructive pulmonary disease and diabetes has increased dramatically.

Multiple Causes of Death in Older Adults

Mortality in older adults results from multiple contributing causes, even if one cause can be considered primary. One study of the predictors of 5-year mortality in older adults found that numerous types of health indices contribute: sociodemographic characteristics, health habits, cardiovascular risk factors, clinical and subclinical diseases, physical disability, and cognitive impairment (Table 22-2). After taking these risk factors and conditions into account, age itself becomes substantially less important as a predictor of mortality, up until the age of 85 years.

Disease Frequencies Rise with Increasing Age

The frequency of almost all chronic diseases increases with age, both before and after 65 years of age. For example, arthritis is reported by about 7% of adults aged 18 to 44 years, about 30% of adults aged 45 to 64 years, and about 50% of adults 65 years and older in 2007. The proportion of people who report very good or excellent health decreases with increasing age, from about 70% of persons aged 18 to 44, to about 55% of persons aged 45 to 64, to about 40% of persons 65 years and older. The prevalence of chronic diseases, especially for arthritis, diabetes, and hypertension, is higher in African Americans than in whites in the oldest age groups.

In addition to clinical diseases, subclinical disease is common in older adults. Among the 6000 men and women aged 65 years and older who participated in the Cardiovascular Health Study, 31% had evidence of clinical cardiovascular disease, whereas another 37% had subclinical disease by a variety of noninvasive measures. For example, brain infarct-like lesions, found on magnetic resonance imaging in 28% of Cardiovascular Health Study participants without a known history of stroke, are associated with falling, balance problems, and cognitive decline. Overall, subclinical cardiovascular disease is a stronger predictor of the older adults in whom clinical cardiovascular disease will develop than are other classic risk factors.

Onset of Geriatric Conditions

Health status in aging is a result of many factors, including the chronic diseases of aging and many other prevalent "geriatric" conditions that cannot be defined as classic "diseases" because they do not manifest in a single organ system or result from a single pathologic cause. Falls, which occur in one fourth of older adults, result in injuries, fractures, and high risk for disability and mortality (Chapter 24). Severe cognitive impairment, delirium (Chapters 26 and 27), and urinary incontinence (Chapter 25) have a substantial adverse impact on an older person, as does the sensory isolation resulting from hearing and visual impairment; all these conditions are frequent with aging. Frailty, occurring in 7% of community-dwelling older adults, is a geriatric syndrome that leads to heightened vulnerability to stressors and substantially increased risk for disability, falls, and mortality.

Why Geriatric Patients Are Different

Comorbid Conditions

Older patients differ from young or middle-aged adults who have the same disease in many ways. First, as a function of the high prevalences of many diseases, multimorbidity (or the co-occurrence of two or more diseases in the same individual) is common. Of people aged 65 years and older, 50% have two or more chronic diseases. The risk for becoming disabled or dependent increases with the number of diseases present, and some specific combinations of diseases synergistically increase the risk for disability. For example, arthritis and heart disease coexist in 18% of older adults; although the odds of developing disability are increased by 3-fold to 4-fold with either disease alone, the risk for disability increases 14-fold if both are present. Furthermore, one disease, such as cognitive impairment, may mask the symptoms of other important conditions, at least temporarily. Treatment of one disease may also affect another adversely, as in the use of aspirin to prevent stroke in individuals with a history of gastrointestinal bleeding.

Nonspecific Signs and Symptoms

Older adults differ also from younger adults in the greater likelihood that their diseases will have nonspecific symptoms and signs. For example, pneumonia and stroke may be associated with nonspecific changes in mentation as the primary presenting symptom. Similarly, the frequency of silent myocardial infarction increases with increasing age, as does the proportion of patients who manifest a myocardial infarction with a change in mental status, dizziness, or weakness rather than typical chest pain (Chapter 50). As a result, the diagnostic evaluation of geriatric patients must consider a wider spectrum of causes than would generally be considered in middle-aged adults.

Frailty

Another condition that is found primarily in older adults is frailty. Frailty, which is a state of decreased reserves and increased vulnerability to all kinds of stresses, from acute infection or injury to hospitalization, identifies individuals who likely will have a lower tolerance for any new medical or surgical condition. Frailty is thought to be a wasting syndrome with a characteristic clinical presentation, including weakness, poor exercise tolerance, slowed motor performance, low physical activity, and weight loss. Some estimates

indicate that the full syndrome is found in 7% of community-dwelling people aged 65 years and older and in 25% of community-dwelling people 85 years and older. Many institutionalized older adults are also frail. The syndrome of frailty is associated with a high risk for falls, need for hospitalization, poorer recovery after hospitalization, disability, and mortality. A core component of frailty is sarcopenia, or loss of muscle mass associated with aging, which occurs in 13 to 24% of persons aged 65 to 70 years and in 60% of persons 80 years and older. Energy dysregulation and abnormalities in multiple physiologic systems, including inflammation, immune function, hormonal status, and glucose metabolism, underlie the syndrome and decrease the ability to maintain homeostasis in the face of stress. Subclinical disease (e.g., atherosclerosis), end-stage chronic disease (e.g., heart failure, HIV/AIDS), or a combination of comorbid catabolic diseases may precipitate the clinically apparent syndrome. Evidence from randomized, controlled trials shows that resistance exercise, with (or without) nutritional supplements and home-based physical therapy, can increase lean body mass and strength in even the frailest older adults,[1,2] and that weight loss in obese, sedentary older adults has incremental benefit.[3]

Cognitive Impairment

Cognitive impairment, which increases in prevalence as people age (Fig. 22-1; Chapters 26 and 27), is a risk factor for a wide range of adverse outcomes, including falls, immobilization, dependency, institutionalization, and mortality. Cognitive impairment complicates the diagnosis of other medical conditions, necessitates targeted prevention of complications, compromises independence, and requires additional caregiving to ensure safety.

Physical Disability

A serious and common outcome of chronic diseases of aging is physical disability, defined as having difficulty or being dependent on others for the conduct of essential or personally meaningful activities of life from basic self-care (e.g., bathing or toileting) to tasks required to live independently (e.g., shopping, preparing meals, or paying bills) to a full range of activities considered to be productive or personally meaningful (Chapter 23). Among older adults, 37% report difficulty with tasks requiring mobility, and this difficulty with mobility predicts the future development of difficulty in instrumental activities of daily living (IADL; household management tasks) and activities of daily living (ADL; basic self-care tasks). In community-dwelling persons aged 65 years and older, difficulty with IADLs is reported by 20%, and difficulty with ADLs is reported by 11%; for both, the prevalence increases with age. People who have difficulty with IADLs and ADLs are at high risk of becoming dependent. Of persons older than 65 years, 3.5% reside in nursing homes, largely as a result of dependency in IADL or ADL (or both) secondary to severe disease. Generally, women live more years with disability, whereas men who become similarly disabled are more likely to die at a younger age. Although physical disability is primarily a result of chronic diseases and geriatric conditions, its onset and severity are modified by other factors, including treatments that control the underlying diseases, physical activity and rehabilitation, nutrition, smoking, and community-based services. Many intervention trials indicate that some disability can be prevented or its severity decreased.[4]

Relationships among Factors

Multimorbidity, frailty, and disability are recognized as distinct clinical entities (Fig. 22-2), although they are related in the same causal pathway. Multimorbidity may be a risk factor for frailty, and both are risk factors for disability. A vicious cycle may exist whereby inactivity resulting from disability precipitates or worsens frailty.

Thus, the health status of older adults includes a broader spectrum of issues than is found in middle-aged or younger patients, including prevalent chronic disease, recurrent disease, multimorbidity, and geriatric conditions, each of which can be an independent problem or interact with other problems

TABLE 22-2 PREDICTORS OF 5-YEAR AND LONG-TERM MORTALITY IN MEN AND WOMEN 65 YEARS AND OLDER IN THE CARDIOVASCULAR HEALTH STUDY*

RISK FACTOR CATEGORY	FIVE-YEAR MORTALITY PREDICTORS†	LONG-TERM MORTALITY PREDICTORS‡
Sociodemographic	Age (older) Gender (male) Income (<$50,000/yr)	Age (older) Gender (male) Race (black)
Anthropometric	Weight (lower)	Weight (lower)
Health habits	Physical activity (low) Smoking (pack years)	Physical activity (low) Smoking (pack years)
Cardiovascular risk factors	Brachial systolic blood pressure (elevated) Posterior tibial artery blood pressure (reduced) Diuretic use (in persons with severe CHF or liver disease) Fasting blood glucose (higher)	Fasting blood glucose (higher)
Serum measures	Albumin (lower) Creatinine (higher)	Albumin (lower) Creatinine (higher) IL-6 (greater) ApoE e4 allele
Clinically manifested disease	CHF	CHF Coronary heart disease
Subclinical disease, measured noninvasively	Forced vital capacity, mL (lower) Major ECG abnormality Ejection fraction abnormal Aortic stenosis (moderate to severe) Stenosis (maximal) of the internal carotid artery (greater)	Forced vital capacity, L (lower) Major ECG abnormality
Consequences of disease	Difficulty with instrumental activities of daily living (≥2) Cognitive impairment (greater) Poor self-assessed health	Difficulty with instrumental activities of daily living (≥2) DSST score (lower) Poor self-assessed health

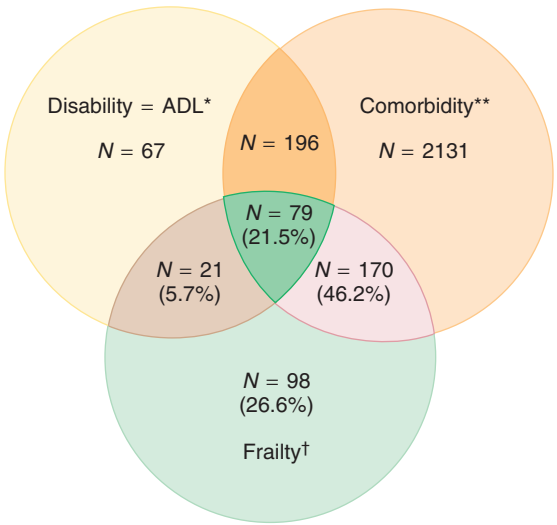

FIGURE 22-2. Overlap of frailty, disability, and comorbidity in community-dwelling older adults participating in the Cardiovascular Health Study. The total represented was 2762 subjects who had comorbidity, disability, or frailty, or any combination of these conditions. **N* = 363 with a disability in activities of daily living (ADL); of these, 100 were frail. ***N* = 2576 with comorbidity, defined as two or more of the following nine diseases: myocardial infarction, angina, heart failure, claudication, arthritis, cancer, diabetes, hypertension, and chronic obstructive pulmonary disease. Of these, 249 were also frail. †*N* = 368 frail subjects. (Adapted from Fried LP, Tangen CM, Walston J, et al. Frailty in older adults: evidence for a phenotype. *J Gerontol A Biol Sci Med Sci*. 2001;56:M146-M156.)

to cause disability, dependency, or death. There is also, however, great heterogeneity in health status among older adults, with robust, independent individuals even in the oldest ages. Because of this heterogeneity, older patients may require primary, secondary, or tertiary preventive health care (Chapter 23) and an individualized titration of therapeutic and palliative care tailored to their individual health status, goals, and inherent risk. Overall, preventive health care is effective in older adults (Chapters 13 and 14), and attention to clinical practices and health habits—from immunization to physical activity—can prevent adverse outcomes into the oldest ages. Preventive measures should also be targeted to situations of acute stress (e.g., hospitalization or immobilization), when the risk of decline in function is high. Health status can change rapidly as people age, so clinical care, prevention, and services must evolve in concert with the health and function of the patient. Further, there is mounting evidence that social engagement, along with physical, cognitive, and social activity, can modify key health outcomes such as cognitive function and potentially frailty and disability.

GERIATRIC ASSESSMENT

DAVID B. REUBEN

Geriatric assessment is a broad term used to describe the evaluation of older patients, a process that recognizes the diverse medical and psychosocial conditions that influence the health status of older persons. In addition to the diseases that are common in the elderly population, these influences include social, psychological, and environmental factors. Geriatric assessment can range from brief screens by individual clinicians to an intensive interdisciplinary process that includes both evaluation and management.

Three fundamental concepts guide geriatric assessment and the resulting medical management. At the core of geriatric assessment is functional status, both as a dimension to be evaluated and as an outcome to be improved or maintained. A second overarching concept guiding geriatric assessment is prognosis, particularly life expectancy. Finally, geriatric assessment must be guided by the patient's goals.

FUNCTIONAL STATUS

Functional status can be viewed as a summary measure of the overall impact of health conditions in the context of an elderly person's environment and social support network. The underlying framework of functional status is a hierarchy of increasing complexity, beginning with specific physical movements (e.g., lifting, walking) that are integrated into higher level activities (e.g., fulfilling occupational and social roles). Impairment of functional status can be triggered by the onset of disease, deconditioning, changes in social support or environment, and advanced age.

Most commonly, older adults' functional status is assessed at two levels: activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs refer to self-care tasks such as bathing, dressing, toileting, maintaining continence, grooming, feeding, and transferring. Dependency in these tasks, which is present in up to 10% of older persons, usually requires full-time help at home or placement in a nursing home.

IADLs refer to tasks that are integral to maintaining an independent household, such as using the telephone, doing laundry, shopping for groceries, driving or using public transportation, preparing meals, taking medications, performing housework, and handling finances. Dependency in IADLs is more common, and almost 20% of persons aged 75 years or older are impaired in at least one task. With the progressive loss of multiple IADL functions, older persons find it more difficult to remain in their homes. Accordingly, many social services (e.g., meals-on-wheels, homemaker services, transportation services) are available to compensate for these deficiencies. A move to an assisted living facility can provide most IADL functions, but many facilities do not routinely provide assistance with ADLs except at an additional cost. In the United States, the costs of assisted living facilities are not covered by Medicare.

At a higher level of function, advanced activities of daily living (AADLs) refer to the ability to fulfill societal, community, and family roles, as well as participate in recreational or occupational tasks. These advanced activities vary considerably from individual to individual but may be valuable in monitoring functional status before the development of disability.

The choice of functional assessment tool depends on the characteristics of the population being assessed. For example, nursing home residents are almost always completely dependent in IADLs, so the focus should be on assessing ADLs and other basic dimensions of health. Hospitalized older persons should be assessed with regard to their prehospitalization functional status to provide insight into what may be achievable, as well as their functional status at the time of discharge to identify any existing gap and facilitate plans to close it.

Functional status is usually measured by self-report or proxy report. However, physical and occupational therapists often add objective information using structured clinical examinations or assessments. In addition, dimensions such as mobility and balance that contribute to function can be assessed by objective measures (described later).

Functional status should be assessed periodically: at the time of an initial visit, after a major illness, and at the time of social milestones, such as the illness of a spouse or a change in living or working situation. Changes in functional status should always prompt further diagnostic evaluation and intervention unless the change is expected and reflects a trajectory that is consistent with the patient's wishes. Measurement of functional status can be valuable in monitoring response to treatment (especially of chronic diseases) and can provide prognostic information that is useful in planning short- and long-term care.

PROGNOSIS

Life expectancy affects both the assessment process and the management decisions based on that assessment. For some older patients, comorbidities can worsen prognosis, such that screening tests (e.g., mammography) and treatments (e.g., for hypertension) with demonstrated effectiveness would not be beneficial within the expected survival period.

Clinicians can estimate remaining years of life by age, gender, and race using life tables (Table 23-1). These tables, however, do not consider clinical characteristics or functional status, which can lead to wide variations in how long an individual patient will live.

PATIENT GOALS

As people age, their current and future health may become a prominent factor in determining and achieving their life goals. Among very old patients, goals may be limited to achieving a functional or health state (e.g., being able to walk independently), controlling symptoms (e.g., pain, dyspnea), maintaining their living situation (e.g., remaining at home), or short-term survival (e.g., living long enough to reach a personal milestone, such as an upcoming holiday). Sometimes the goals of patients and physicians differ. For example, a patient may want a cure, whereas the physician believes that only symptom management is possible. Conversely, the physician may believe that a better outcome is possible, but the patient declines to pursue the recommended path (e.g., hip replacement to restore mobility).

COMPONENTS OF GERIATRIC ASSESSMENT

Geriatric assessment begins with a medical evaluation. Some aspects (described later) that are rarely abnormal in younger adults (e.g., mobility, cognition) may cause substantial morbidity in older persons. In addition, some clusters of abnormal findings, such as muscle wasting, poor hygiene, bruises, pressure sores, and contractures, should raise the suspicion of elder mistreatment, neglect, or abuse. In such cases, patients should be questioned and examined without family members or caregivers present. Patients should then be queried whether anyone has threatened or hurt them, whether they have been receiving enough care, and whether anyone has taken their things. Answers to these questions may provide confirmatory information and prompt a report to adult protective services.

Nonmedical assessments are also important because they can identify problems that should be addressed and may be key to achieving the patient's goals. In addition to an assessment of functional status, older persons' environmental, financial, and nonfinancial support should be assessed. In some situations, particularly when older persons become acutely ill or experience caregiver stress or loss of a loved one, assessment of spiritual needs, with appropriate referral, may be valuable.

TABLE 23-1 LIFE EXPECTANCY (IN YEARS) FOR OLDER PERSONS BY AGE, RACE, AND SEX

	White		*Black*	
AGE	**MALE**	**FEMALE**	**MALE**	**FEMALE**
65	17.2	20	15.2	18.6
70	13.7	16.2	12.4	15.3
75	10.7	12.8	9.9	12.2
80	8.1	9.7	8.0	9.6
85	6.0	7.1	6.3	7.5
90	4.3	5.1	4.9	5.7
95	3.1	3.6	3.8	4.3
100	2.2	2.5	2.9	3.2

Advance Directives

Clinicians should discuss older patients' preferences for specific treatments while they still have the cognitive capacity to make these decisions. Patients should be asked to identify a spokesperson to make medical decisions for them if they cannot speak for themselves. This information should be conveyed through a durable power of attorney for health care, which also allows patients to specify treatments they do not want. Many states have allowed the use of Physician Orders for Life-Sustaining Treatment, a specific advance directive that documents a patient's end-of-life treatment preferences and serves as an order sheet. The standardized form is signed by both the physician and the patient and must be honored in all settings of care.

Medical Assessment

The medical assessment includes vision; hearing; cognition; mood and affect; falls, mobility, and balance; medication review; nutrition; and urinary incontinence. Numerous screening instruments have been developed that assess many of these dimensions. Other important medical components of geriatric assessment include a review of the patient's medications and a determination of whether preventive services are up-to-date.

Vision

Each of the four major eye diseases—cataract, age-related macular degeneration, diabetic retinopathy, and glaucoma (Chapter 431)—increases in prevalence with age. Moreover, presbyopia is virtually universal, and the vast majority of older persons require eyeglasses. Visual impairment has been associated with increased risk of falls, functional and cognitive decline, immobility, and depression. Corrective lenses or other treatments may restore vision or prevent further decline of visual function.

A single question can be used to screen for visual impairment: Do you have difficulty driving, watching television or reading, or doing any of your daily activities because of your eyesight, even while wearing glasses?

The Snellen eye chart is the standard method of screening for visual acuity. The patient is asked to stand 20 feet from the chart and read letters. Inability to read letters on or below the 20/40 line with their best-corrected vision (using glasses) indicates the need for further evaluation.

Hearing

Hearing loss (Chapter 436), which affects 30% of community-dwelling older adults older than 65 years and 75% of residents living in nursing home settings, is associated with reduced cognitive, social, emotional, and physical functioning. When hearing loss is detected, amplification by hearing aids or assistive listening devices can improve quality of life and functional status.

To assess hearing, the physician can administer the whisper voice test, which involves whispering three different random words in each ear at distances of 6, 12, and 24 inches from the patient's ear and then asking the patient to repeat the words. Patients who fail the screen—that is, are unable to repeat half the whispered words correctly—should be referred to an audiologist for further evaluation. Alternatively, the Hearing Handicap Inventory for the Elderly, a 10-item self-report instrument, has been used widely.

A more accurate screening tool for hearing impairment is the Welch Allyn AudioScope. This handheld otoscope has a built-in audiometer that can be set at different levels of intensity. A pretone at 60 dB is delivered to the patient, and then four tones of 500, 1000, 2000, and 4000 Hz at 40 dB are presented. The inability to hear either the 1000- or 2000-Hz frequency in both ears or both the 1000- and 2000-Hz frequencies in one ear indicates a positive screen and identifies the need for formal audiometric testing.

Cognitive Assessment

The incidence of dementia (Chapters 26 and 409) increases with age, especially among those older than 85 years. Early detection of memory problems can lead to the identification of treatable conditions that contribute to cognitive impairment and the development of a proactive management plan with the patient's full participation.

The most commonly used screen is the Mini-Mental State Examination (MMSE), a 30-item interviewer-administered assessment of several dimensions of cognitive function (see Table 26-4). However, the MMSE is too long for most practitioners to incorporate routinely into their clinical practices, and the instrument must be purchased for use. Several shorter screens have also been validated, including recall of three items at 1 minute and the Mini-Cog test (see Table 26-5), which combines three-item recall and the clock-drawing test.

Another component of cognitive assessment is decision-making capacity. In cognitively intact older persons, capacity is assumed. However, among those with cognitive impairment, decision making must be determined before many treatments are initiated. As a rule, capacity is specific to the decision the patient is being asked to make. Ask the following questions to determine a patient's decision-making capacity:

- Can the patient make and express personal preferences at all?
- Can the patient comprehend the risks and benefits?
- Does the patient comprehend the implications?
- Can the patient give reasons for the alternative selected?
- Are supporting reasons rational?

If the answer to all these questions is yes, the patient is competent to make the decision at hand. If not, then a surrogate (the durable power of attorney for health care, if the patient has identified one) should make the decision. If a durable power of attorney for health care has not been identified, the decision can be made by a family member, friend, or caregiver who knows the patient well. The order of surrogates is determined by state law. If no one is available, the health care provider should make the decision based on the patient's known value system or what the health care provider believes to be in the best interest of the patient.

Mood and Affect

Although major depression (Chapter 404) is no more common among the elderly than among the younger population, minor depression and other affective disorders are common and cause considerable morbidity. Moreover, depression may present atypically, and it may be masked in patients with cognitive impairment or other neurologic disorders such as Parkinson's disease (Chapter 416).

A two-item version of the Patient Health Questionnaire (PHQ-9) can effectively screen for depression symptoms. The screener asks the patient: Over the past 2 weeks, how often have you been bothered by any of the following problems?

- Little interest or pleasure in doing things.
- Feeling down, depressed, or hopeless.

Responses are scored as follows: 0 = not at all, 1 = several days, 2 = more than half the days, 3 = nearly every day. Persons who score a total of 3 points or higher on the two-item screen have a 75% probability of having a depressive disorder. More detailed information can be gathered using instruments such as the Geriatric Depression Scale.

Falls, Mobility, and Balance

Approximately one third of community-dwelling persons older than 65 and half of those older than 80 fall each year. Ten percent of these falls result in a serious injury. Patients who have fallen or have gait or balance problems are at higher risk of another fall. Performing a falls assessment (measuring orthostatic blood pressure; assessing vision; reviewing medications; and testing balance, gait, and lower extremity strength) and treating risk factors for falling can reduce falls by 30 to 40%.

All older patients should be asked at least annually if they have fallen, and frail older persons should be asked about falls at every visit. In addition, asking about fear of falling can identify patients at risk of future falls.

Patients who have fallen or have a fear of falling should have their balance and gait assessed by direct observation of their ability to perform specific tasks. Tests of balance include the ability to maintain a side-by-side,

semitandem, and full-tandem stance for 10 seconds; resistance to a nudge; and stability during a 360-degree turn. Quadriceps strength can be assessed by observing an older person rising from a hard armless chair without using his or her hands.

In addition, direct qualitative and quantitative observation of gait to determine stability is a quick and important component of assessment. Qualitative aspects include evaluation of hesitancy; sway; step length, height, symmetry, and continuity; and path deviation. Gait speed is also a helpful marker for recurrent falls. Patients who take more than 13 seconds to walk 10 meters are more likely to have recurrent falls.

The timed "up-and-go" test combines some features of strength and gait. It is a timed test of the patient's ability to rise from a standard armchair, walk 3 meters (10 feet), turn, walk back, and sit down again. Patients who take longer than 20 seconds to complete the test should receive further evaluation.

Medication Review

Older persons often see several different health care providers who prescribe multiple medications that increase the risk for drug-drug interactions and adverse drug events. At a minimum, the clinician should review the patient's updated and accurate medication list at each visit. A good method of detecting potential problems is to have patients bring in all their medications (prescription and nonprescription) in their bottles. Entering a patient's medication list into commercially available computer drug interaction programs can help prevent adverse events.

Nutrition

Malnutrition in older adults includes obesity (Chapter 227), undernutrition (Chapter 221), and specific vitamin deficiencies (Chapter 225). Obesity in older adults is defined as a body mass index (BMI) of 30 kg/m^2 or greater. High BMI is associated with poorer function and more comorbidities, such as type 2 diabetes mellitus (Chapters 236 and 237), osteoarthritis (Chapter 270), hyperlipidemia (Chapter 213), coronary artery disease (Chapter 51), and sleep apnea (Chapter 100).

At the initial visit, patients should be weighed and asked about weight loss in the previous 12 months. They should be weighed at all follow-up visits. BMI should be calculated on the initial visit and periodically thereafter (e.g., yearly or when a change in weight suggests the need to recalculate). Serum markers, including serum albumin, prealbumin, and cholesterol levels, are nonspecific indicators of nutritional status and can be affected by inflammatory states, physiologic stress, and trauma.

Weight loss of 4% or more over 12 months predicts increased mortality and should prompt an evaluation of medical (e.g., malignancy, gastrointestinal disorders, hyperthyroidism, diabetes), psychiatric (e.g., depression, dementia), dental, and social or functional (e.g., poverty, inability to shop or prepare meals) causes.

Urinary Incontinence

Approximately one third of community-dwelling older adult women have some degree of urinary incontinence (Chapter 25), and 75% of older men have abnormal urinary tract symptoms. Complications of incontinence include skin irritation, pressure ulcers, urinary tract infections, sleep disruption, and falls. Identification of urinary incontinence is important because effective behavioral and pharmacologic treatments are available.

A simple screen for urinary incontinence asks the following question: Have you had urinary incontinence (do you "lose" your urine) to the extent that it is bothersome and you would like to know how it can be treated? This may be valuable in determining which patients want further evaluation and therapy. Patients who answer yes should be asked how much urine is leaked, how much it interferes with daily life, and when the leakage occurs. Further evaluation and treatment depend on whether the incontinence is overflow incontinence, urge incontinence, or stress incontinence (see Table 25-3).

PREVENTIVE SERVICES

Preventive services include lifestyle advice, screening tests to detect asymptomatic disease, and vaccinations. Recommended adult immunization schedules include annual influenza vaccination, one-time pneumonia vaccination, one-time pneumococcal vaccination, one-time herpes zoster vaccination (even if the patient reports a past episode of herpes zoster), and tetanus toxoid vaccination every 10 years (Chapter 17).

To help the clinician decide what is appropriate for a specific patient, the U.S. Preventive Services Task Force has created an interactive website (*http://epss.ahrq.gov/ePSS/search.jsp*) with recommendations based on the patient's age, gender, tobacco use, and current sexual activity (Chapter 14). For younger elderly persons, recommendations include screening for blood pressure, diabetes, hyperlipidemia, obesity, alcohol misuse, colorectal cancer, and osteoporosis, as well as breast cancer in women, with appropriate counseling and treatment if these disorders are detected. Aspirin may be recommended to prevent cardiovascular disease in this population. Other recommendations depend on patient-specific risk factors.

With increasing age, fewer preventive services are recommended because of limited life expectancy and greater comorbidities. Accordingly, some preventive measures (e.g., aspirin to prevent cardiovascular disease) and cancer screenings are not recommended in the very elderly. When the evidence base for preventive services is sparse, decisions should be individualized, based on the patient's personal values, goals, and preferences.

NONMEDICAL ASSESSMENTS

Environmental Assessment

Assessing a patient's environment includes evaluating three components: the person's ability to access community services (e.g., getting to the bank and stores if the patient cannot drive), the safety of the physical environment, and the appropriateness of the living situation for the person's functional ability and cognitive status. A brief screen for safety of the physical environment can be accomplished by using a checklist that is in the public domain (*http://www.cdc.gov/ncipc/pub-res/toolkit/Falls_ToolKit/DesktopPDF/English/booklet_Eng_desktop.pdf*). For home-bound older patients, a home safety evaluation by a home health agency is more appropriate.

Social Support Assessment

When older persons become frail, the adequacy of their social support network may be the determining factor in whether they can remain at home or need institutionalization. A brief screen of social support includes taking a social history, including asking who would be available to help if the patient becomes ill. For patients with functional impairment, the clinician should ascertain who can help the patient perform ADLs or IADLs. Early identification of problems with social support can help avoid crisis situations if the patient has a sudden medical or functional decline. Caregivers should be screened periodically for symptoms of depression or caregiver burnout and referred for counseling or support groups if necessary.

Financial Assessment

Although clinicians do not have the training or expertise to explore financial resources in detail, knowing the patient's insurance status may be helpful. For example, patients with Medicaid coverage may qualify for additional medical or social support benefits. Some may be eligible for other state or local benefits, depending on their income. Others may have long-term care insurance or veterans' benefits that can help pay for caregivers, obviating the need for institutionalization.

A STRATEGIC APPROACH TO GERIATRIC ASSESSMENT FOR THE PRACTICING CLINICIAN

Although assembling an interdisciplinary assessment team is beyond the capability of most practitioners, even small group practices can use teamwork and simple practice design to perform geriatric assessments efficiently and comprehensively. These assessments can lead to local implementation of or referral to comprehensive care models that can improve the outcomes of elderly individuals with a variety of chronic conditions.[1,2] Because of time constraints, screening is increasingly delegated to staff and to patients and their families using standing orders, forms, and questionnaires (Table 23-2). For example, previsit questionnaires can be used to gather information about past medical and surgical history; medications and allergies; social history, including available social support resources, preventive services, ability to perform functional tasks, and need for assistance; home safety; and advance directives. In addition, the previsit questionnaire can include specific questions that assess vision, hearing, falls, urinary incontinence, and depressive symptoms. A reasonable approach is to assess these issues annually beginning at age 75 years. Persons who are younger than 75 but have multiple comorbidities should also be screened and reassessed annually. In addition, some elements of geriatrics assessment (assessing ADLs and IADLs; gait, balance, and falls; mood and affect; and cognition) should be performed after major illnesses, especially those requiring hospitalization.

24

COMMON CLINICAL SEQUELAE OF AGING

KENNETH L. MINAKER

EPIDEMIOLOGY

Increased longevity throughout the world is influencing medical care dramatically as more and more older individuals survive with more complex medical conditions. Although some elderly individuals present classically with single-system disease, others have presentations and responses to treatments that are different from those in younger patients. This variation in presentation and behavior of illnesses, which is due to the combined effect of aging and comorbid disease, must be understood if elderly patients are to receive successful care.

PATHOBIOLOGY

Age-associated changes in health and disease are the result of (1) variations in the underlying physiologic changes that occur with age; (2) the presence of other diseases and medical conditions that have developed over time; (3) genetic predispositions for certain diseases; (4) lifestyle factors, including health-seeking behavior, diet, exercise, and exposure to medications and toxins; and (5) the variability intrinsic to diseases and medical conditions in general. Although no single hypothesis fully explains the process of aging at this time (Chapter 22), two major approaches have emerged (Table 24-1). The first concerns programmed causes, which are dominated by genetic theories. The second concerns stochastic causes, so-called process-of-living theories, in which genetic or environmental influences limit viability.

Spectrum of Changes Produced by Aging Processes

Perhaps the most important observation regarding normal aging is how much does not change. Most hormone levels, liver enzyme activities, electrolyte levels, body temperature, and basal glucose concentration remain constant throughout the lifespan. Long-term studies have indicated that there is no age-related anemia (Chapter 161), although the hematocrit declines slightly in men presumably because of the age-related decline in testosterone.

The passage of time results in changes that are not due to aging per se but rather may be considered "dose-time" related. For example, prolonged exposure results in the emergence of abnormalities and illnesses, such as skin cancer due to cumulative actinic injury (Chapter 210). Much of the lifetime exposure to sun is received before the age of 20 years, yet the resulting cancers follow decades later. Another example is polycystic kidney disease, which is an inheritable condition that does not appear until well into adulthood (Chapter 129); the passage of time allows the "full expression" of the genetic phenotype, but aging itself is not the key factor.

Some conditions become less likely with advancing age because of changes in the immune system. Immune disorders such as systemic lupus erythematosus (Chapter 274) and multiple sclerosis (Chapter 419) rarely appear in late life, presumably because changes in the immune system lead to less aggressive autoimmune activity. Similarly, although many cancers are more common in elderly people, many of the most aggressive tumors occur at a young age, suggesting that immune tolerance develops with advancing age.

TABLE 24-1 PATHOBIOLOGY OF AGING

THEORY	DEFINITION	CAUSE: GENETIC (G) OR ENVIRONMENTAL (E)	
PROGRAMMED THEORIES			
Programmed senescence	Aging results from gene interference with the ability of the cells to reproduce	Master clock, cancer protection	G
Hormonal	Biologic clock alters hormone secretion, resulting in tissue changes	Decrease in levels of insulin-like growth factor-I and the hormones estrogen, testosterone, DHEA, and melatonin	G
Immunologic	T-cell function declines, increasing the chances for development of infections and cancer	Alteration in the cytokines that are responsible for communication between immune cells	G
Telomere shortening	Shortening of telomeres in somatic cells lessens the ability of cells to divide	Cells cannot divide	G, E
STOCHASTIC THEORIES			
Metabolic rate	The higher the basal metabolic rate (the rate at which the body, at rest, uses energy), the shorter the lifespan	Energy demands to maintain basal metabolism	G
Glycation	Glycation (browning) causes proteins to be joined, resulting in rigidity and decreased function	Elevated glucose	G, E
Somatic mutation	Mutations in genes occur with aging, eventually causing cells to stop functioning	Errors in the transmission of genetic messages over time	G
Wear and tear	Parts of cells wear out over time	Accumulated debris mechanically disrupts cell function	E
Oxygen free radicals	Tissue damage is caused by free radicals, such as superoxide or hydroxyl radicals; this is a specific form of the wear-and-tear theory	Oxygen free radicals are unstable chemical compounds that can oxidize cell components such as DNA and proteins	E

DHEA = dehydroepiandrosterone.

Physiologic aging modulates the ways in which illnesses cause signs and symptoms. The elderly individual with hyperthyroidism often presents not with the systemic findings of agitation, irritability, hyperactivity, hyperphagia, and increased bowel movements but rather with apathy, anorexia, and atrial fibrillation (Chapter 233). The underlying pathophysiologic process may be no different, but age-related changes in physiology alter the body's sensitivity to dysfunction and influence the clinical presentation.

The most important physiologic change of aging is the predisposition to more generalized clinical syndromes and more severe disease. The lung function of a healthy 70-year-old is about 50% that of a 30-year-old (Chapters 83 and 85). Renal function commonly declines by 50% or more by the age of 70 years (Chapter 117). The resultant lack of physiologic reserve capacity does not affect day-to-day function but can affect the ability to recover from an extreme illness that exhausts the body's reserve capacity.

Geriatric syndromes emerge from these age-related changes. Many systems that maintain our upright posture are compromised by age, leading to increased postural sway. An older individual is much more likely to fall after a slip or a push. The consequences of that fall are more serious because of the age-related loss of bone mass (Chapter 251), resulting in fall-related fractures and spinal cord injuries.

Some physiologic changes imitate illness when they may be a normal part of aging. Diabetes mellitus may "appear" and "disappear" in elderly people (Chapters 236 and 237). The ability of insulin to stimulate glucose uptake declines with age and usually is manifested as postprandial hyperglycemia, but with normal fasting insulin and glucose levels. Under stress situations, older individuals can appear to be diabetic, but when the stressful situation is relieved, they no longer have chemical evidence of diabetes. Nevertheless, this loss of physiologic reserve understandably contributes to the increasing prevalence of diabetes with advancing age.

The age-related changes that make elderly people more vulnerable in daily life are often subtle. Older individuals are more likely to develop hypothermia or hyperthermia (Chapter 109) during extreme environmental exposure because of neurologic and thermoregulatory changes. The loss of brain stem neurotransmitters in older persons not only may cause a senile gait pattern but also predisposes to genetically determined conditions such as Parkinson's disease (Chapter 416). Decreases in the function of the frontal lobe inhibitory center predispose to urgency of urination.

Some age-related changes cause specific medical sequelae. Menopause (Chapter 248) is a normal aging process that produces symptoms and predisposes to future bone loss, urogenital atrophy, and atherosclerosis. Senile cataracts are caused by post-translational modifications in lens proteins combined with the inability of the lens to dispose of breakdown products associated with these processes; as a result, the lens becomes stiffer, thicker, and more opaque with age (Chapter 431).

EFFECTS OF AGING ON SPECIFIC ORGANS AND SYSTEMS

Cardiovascular System

Aging and Its Clinical Sequelae

Many important physiologic changes occur in the aging heart and help explain common age-associated cardiac disorders. Perhaps the most important physiologic change is the delay in left ventricular filling, which declines 50% between the ages of 20 and 80 years. Cardiac filling becomes more dependent on active filling late in diastole during atrial contraction (Chapter 52). This phenomenon commonly is related to thickening and stiffening of the left ventricular wall. Under normal conditions, systolic function remains unchanged, but the thickened ventricle will not produce normal output when volumes are low or be able to avoid elevated filling pressures and the resulting pulmonary congestion when volume is high. As a result, brain natriuretic peptide levels increase with age as myocardial sensors detect greater pressures in the heart.

The resting heart rate slows slightly with advancing age, and maximal and submaximal exercise-induced heart rates show an age-related decline. The loss of sinus node pacemaker cells—up to 90% at 80 years—contributes to these changes. There also are changes in central and baroreflex-mediated heart rate control (Chapter 62). Heart valves thicken and stiffen, particularly in the mitral and aortic locations (Chapter 75). The functional significance of heart valve stiffening is minimal, but 25% of older individuals have flow murmurs (Chapter 50). The aorta dilates and its walls thicken as medial walls calcify; with this loss of elasticity, there is a secondary increase in systolic blood pressure (Chapter 67). The arteriosclerosis that is due to intimal disease further causes arterial walls to thicken, calcify, and lose their elasticity, thereby predisposing aging vessels to occlude or rupture (Chapter 70).

In most industrialized countries, there is a progressive increase in blood pressure with advancing age (Chapter 67). In general, systolic blood pressure increases after the age of 30 years, continues to rise until the mid-70s, then tends to fall slightly through the 80s and 90s. Diastolic blood pressure tends to parallel the usual increase in body weight that peaks in the early 50s in men and the early 60s in women; diastolic pressures subsequently fall slightly in older age. These changes in blood pressure are not universal, suggesting varied genetic and environmental causes, such as stress, sodium and potassium intake, and obesity.

Age-Related Cardiovascular Syndromes

Although atherosclerosis is the most important cause of symptomatic cardiac disease in elderly people, age-associated vascular stiffness predisposes to left ventricular stiffness, impaired diastolic filling, and the clinical syndrome of diastolic heart failure (Chapter 58). The most common arrhythmia in older

individuals is atrial fibrillation (Chapter 64), which may occur in one third of older individuals undergoing surgery and may affect 4% of community-dwelling elderly individuals. Although thyroid disease, coronary artery disease, valvular heart disease, and intrinsic conduction system disease are common causes, atrial fibrillation in elderly people is often "lone" atrial fibrillation without a detectable underlying illness.

The combination of sensitivity to filling volumes and impaired heart rate response to stress may explain the increasingly prevalent syndrome of postural hypotension that is present in 20% of older individuals (Chapter 62). Postural hypotension is also common in elderly individuals after large meals; during infections severe enough to depress salt and water intake; and during volume-depleting stresses, such as diarrhea, diuretic therapy, and bowel preparation for colonoscopy. Stiffening of vessels in which baroreceptors reside also reduces the ability to modulate blood pressure with advancing age.

Perhaps the most important principle in the approach to cardiovascular signs and symptoms with advancing age is to recognize the narrowed homeostatic capacity of elderly people. Volume status must be managed carefully, attention should be paid to standing as opposed to sitting blood pressure in patients predisposed to postural hypotension, side effects of medications must be anticipated and monitored, and cardiovascular instability must be expected during almost any major illness that an older person may experience.

Respiratory System

The most characteristic change in the chest wall with advancing age is stiffening (Chapter 85). Cartilages thicken and calcify, and spinal ligaments and joints become stiffer. The primary internal change in the lungs is the loss of the elastic recoil. The result is a modest expansion of the chest wall with the appearance of a mild barrel chest. Although resting lung mechanics do not appear to change in any major way, maximal breathing capacity declines by approximately 40%. At the alveolar level, the capacity to exchange oxygen and carbon monoxide decreases by approximately 50% between the ages of 30 and 65 years, in part as a result of ventilation-perfusion mismatching (Chapter 85). Although these changes are not noticeable at rest, individuals experience fatigue or shortness of breath when the respiratory system is under stress (e.g., during exercise or major illness). Pulmonary reflexes such as coughing and ciliary function decrease, predisposing elderly individuals to the pooling of secretions.

These changes do not produce substantial abnormalities in resting oxygen saturation, but they produce a steady decline in arterial Po_2. The arterial Po_2 of many individuals older than 80 years is about 70 to 75 mm Hg. As with other age-related physiologic findings, these changes do not interfere with function under resting conditions but dramatically affect survival during severe respiratory illness.

Age-Related Respiratory Syndromes

The major clinical impact of normal physiologic aging in the lungs is an earlier appearance of shortness of breath as a warning signal of underlying disease. Myocardial infarction and heart failure can present primarily with shortness of breath, mainly owing to age-related mechanical changes, an inability to clear blood from the lungs, and a decline in resting pulmonary function to near the threshold for clinical hypoxia. Aspiration pneumonia increases with age in association with impaired swallowing, reflux, and reduced clearance of lung secretions.

Gastrointestinal System

A broad series of changes occur in gastroenterologic tissues, but the redundancy of overall gastrointestinal function usually prevents clinical symptoms. Age-related changes in the mouth include slower production of dentine, shrinkage of the root pulp, and decreasing bone density of the jaw. Taste and smell decline progressively with advancing age, with rising thresholds for tasting salt, sweetness, and certain proteins (Chapter 435). The overall net effect is that food may taste more bitter, and more sugar is required before something tastes sweet. Salivary gland function normally does not change with age (Chapter 433). The loss of bone and tongue musculature makes the tongue appear to be enlarged.

The esophagus appears to function relatively normally. The strength of muscle contraction declines, however, and peristaltic waves slow with advancing age. There is also a tendency for the lower esophageal sphincter to become lax (Chapter 140). These changes predispose to aspiration.

The gastric mucosa secretes less acid with advancing age. Although these changes do not appear to affect digestion in most individuals, associated conditions, such as atrophic gastritis, may further decrease the absorption of nutrients to the point of producing illness. Most studies suggest that delayed gastric emptying is a feature of aging, leading to a sense of early satiety, which can impair subsequent food ingestion (Chapter 138).

Liver weight declines by one third between the ages of 30 and 90 years, primarily because of the loss of hepatocytes. The result is a decreased ability to process medications such as benzodiazepines, which require two steps for metabolism, and vitamin K–blocking agents. Doses of drugs often must be adjusted, and their blood levels should be monitored when possible.

Aging is associated with a significant reduction in small intestinal surface area with the consequence of reduced absorption of some dietary components, such as calcium. Colonic function declines with advancing age. Motility up to the rectosigmoid area, measured by passage of markers, does not appear to decline with advancing age (Chapter 138). Distal to this point, however, evacuation is characteristically slower with advancing age. Stool frequency tends to decline, and hardness of stools appears to increase with advancing age. Diverticula are present in approximately 50% of people older than 80 years and are likely to be related to reduced dietary fiber and the resulting greater intracolonic pressure (Chapter 144).

Age-Related Gastroenterologic Syndromes

The most important age-related symptom is constipation (Chapter 138), which may affect 60% of individuals in late life. Obstipation can present atypically with confusion, nausea, and vomiting or as obscure fever resulting from stercoral ulcerations. Perhaps the most common abnormality related to declining hepatic function is increased sensitivity to medications that require hepatic metabolism.

Renal and Urinary Excretory System

Overall kidney size declines by approximately one third, and blood flow through the kidney declines by about 1% per year. Beginning in the late 30s, cortical nephrons appear to drop out and sclerose at a much higher rate than medullary nephrons, creating a hyperfiltration syndrome that limits maximal concentrating capacity (Chapter 117). Resulting functional changes include decreased ability to excrete a salt load, declining glomerular filtration rate, delayed ability to regain sodium and potassium balance during deprivation states, and difficulty in conserving water under situations of dehydration. Excretion of water loads is not strikingly impaired with age, but modest and perhaps clinically significant reductions in acid secretion have been shown in older individuals.

The bladder tends to become more irritable with advancing age and may generate less power during contraction. Because of the delay in sodium excretion and orthostatic changes, nocturia is common; older individuals appear to produce more urine at night than during the day. The most important bladder change may be the slight increase in residual bladder urine volume. Atrophy of vaginal and urethral tissues due to postmenopausal estrogen deprivation predisposes women to urinary tract infections (Chapter 248).

Age-Related Renal and Urinary Tract Syndromes

The age-related increases in asymptomatic bacteriuria and urinary tract infections are almost certainly due to increased residual bladder volume and loss of protective factors in the normal anatomic structures. As the prostate gland grows with advancing age, benign prostatic hypertrophy causes urinary retention in men (Chapter 131). Urinary incontinence (Chapter 25) is more prevalent in women. The kidney is more susceptible to the effects of medications, particularly nonsteroidal anti-inflammatory drugs, which can result in sodium and fluid retention and subsequent hypertension. In elderly individuals, a slight acidemia results from impaired acid excretion and may contribute to the development of osteoporosis.

Dehydration or volume depletion, which is increasingly prevalent with advancing age, often accompanies acute infections and increases the morbidity and mortality of pneumonia or urinary tract infections. Dehydration is the most common fluid and electrolyte disorder in the frail elderly patient because of decreased fluid intake and increased fluid losses. Vomiting and diarrhea are the most common causes of isotonic dehydration. Fever associated with delirium is the leading cause of hypertonic dehydration. Hypotonic dehydration is seen most commonly with overuse of diuretics. Signs and symptoms of dehydration are notoriously vague or absent. Orthostatic tachycardia and hypotension are important clinical findings, and an acute decline in weight may be documented. Perhaps the most useful clinical parameter is a history of having missed one or more meals. A day's food contains about 1 liter of water, which may become a major water source for

older individuals with impaired thirst. Laboratory tests should measure the electrolytes, osmolality, creatinine, and blood urea nitrogen; a blood urea nitrogen–to-creatinine ratio greater than or equal to 25 is suggestive of dehydration.

Anticipation and prevention of dehydration are crucial. Adequate food intake should be maintained. The total water ingested per day in persons over age 70 years ideally should be 3.7 liters for men and 2.7 liters for women. At a minimum, 30 mL of daily fluid intake per kilogram of body weight is recommended. In patients suffering from an acute medical event, it is important to review any long-term medications, particularly diuretics, that may have contributed to dehydration and to define the ethically appropriate approach to future episodes. In terminally ill patients, death from dehydration becomes a natural event in which symptom-focused care relieves discomfort from dry mucous membranes (Chapter 3).

Endocrine System

Growth hormone levels fall with advancing age, with initial loss of nocturnal growth hormone spikes (Chapter 231). These declines contribute to the decreased muscle strength, thinning of bones and skin, and increased central fat associated with aging. It is currently unclear whether replacement of growth factors can induce a permanent reversal of muscle, bone, and skin changes with advancing age.

The production rates and clearance rates of thyroxine, triiodothyronine, and calcitonin appear to be constant with advancing age despite the increased prevalence of thyroid disease in late life (Chapter 233). There is an increase in parathyroid hormone levels, particularly in women, with advancing age, perhaps in compensation for the age-related decline of the kidney's ability to maintain normal levels of phosphorus and calcium in the blood (Chapter 253).

The adrenal glands maintain their ability to secrete cortisone with advancing age (Chapter 234). Dehydroepiandrosterone declines 85 to 90% by the age of 70 years, however, perhaps contributing to impaired immune or cardiovascular function. Renin and aldosterone secretion rates decline progressively with advancing age and do not contribute to the increased rates of hypertension with advancing age.

The insulin content of the elderly pancreas is increased, but the release of insulin in response to stimulation may be blunted with advancing age (Chapters 236 and 237). There is also a concomitant decline in insulin clearance with advancing age, with the net result that plasma insulin levels in response to glucose appear to be relatively preserved. Insulin resistance may increase with advancing age, but glucagon secretion appears to be well preserved.

The ovaries show dramatic declines in estrogen and progesterone as fibrosis and scarring occur. Menopause occurs at an average age of 51 years, with subsequent hot flashes, accelerated bone loss, and atrophy of estrogen-sensitive tissues (Chapter 248). Levels of testosterone decrease in some men beginning around 50 years, but declines do not appear to affect the potency of semen. Sexual function is relatively well preserved, albeit with an increase in the refractory period, increase in the time to arousal, and a loss of tissue turgor (Chapter 242).

Age-Related Endocrine Syndromes

The most important age-related endocrine syndrome occurring with advancing age is menopause (Chapter 248). Most other endocrine changes with age may enhance the prevalence of common disorders seen with aging, especially diabetes.

Immune System

Normal aging produces an obvious decrease in the size of the thymus gland between puberty and 50 or 60 years of age, at which time the gland becomes difficult to identify anatomically. This decrease in size is accompanied by a corresponding drop in thymosin levels, which are related directly to the number of functional T cells found in older adults. T cells also appear to be less active in responding to the presence of foreign proteins, and they tend to reproduce more slowly than those in younger adults. Functional studies of immune responsiveness suggest that although antibody responses are produced by older individuals, they tend to be less robust and less long lasting than in younger individuals (Chapters 44 and 257).

Clinical Syndromes of Aging

There are increased morbidity and mortality associated with influenza and pneumonia with advancing age and reactivation of infections such as tuberculosis and herpes zoster. The decline in immune function also may make it less likely that older adults will develop autoimmune diseases, such as systemic lupus erythematosus.

Vaccine therapy, which is recommended for the prevention of herpes zoster (Chapters 17 and 383), reduces zoster-related adverse effects on functional status and quality of life.[1] It is even more critical to maintain annual immunization against influenza (Chapter 17). Pneumovax and tetanus vaccination are also important in elderly people (Chapter 17).

Hematopoietic System

The pluripotent stem cell and the erythroid and myeloid progenitor cells show no age-related reduction, indicating that there is minimal or no change in basal hematopoiesis during aging (Chapter 159). The aging hematopoietic system is less able to respond to increased demands, however, as evidenced by a slower recovery from anemia and less of a rise of hemoglobin during hypoxia. The older marrow also appears to respond less well to erythropoietin.

Neutrophils from elderly individuals show less prekilling activity and lower levels of lysozyme (Chapter 172), with a significant reduction in signal transduction and less release of inositol 1,4,5-trisphosphate and diacylglycerol during stimulation. During nutritional deprivation, there appears to be impairment in the reserve capacity to kill phagocytosed bacteria, a change that may contribute to the high prevalence of serious bacterial infections among nutritionally compromised elderly patients.

Age-Related Hematopoietic Syndromes

There are no specific syndromes of impaired hematopoiesis, aside from the clinical observation that during a comparable illness stress, hematologic abnormalities are more likely in elderly patients.

Musculoskeletal System

Bone mass and density decrease with age after reaching maximum in the 20s. In women, this loss may be about 1% per year until menopause, when it can increase to 2 to 3% per year (Chapters 248 and 251). By 5 to 10 years after menopause, bone loss returns to a rate of loss of 1% per year, but it may accelerate again in the late 80s. Because men have more bone mass than women do and lose bone mass at a similar rate of about 1% per year, the clinical effects in men are not seen until advanced age.

Tendons and ligaments become less elastic with advancing age, contributing to a higher incidence of rupture, especially of the Achilles tendon, in older individuals. Cartilage and ligaments of the ribs and spine are more likely to become calcified and less elastic.

Muscles reach their ultimate size and strength in the 20s and 30s. By 70 years of age, muscle mass declines by approximately 25% for men and women unless it is offset by exercise. By the age of 80 years, muscle size and strength in most sedentary adults decrease by 30 to 40% from the mid-30s peak. Muscle mass in late life depends on exercise earlier in life to reach a higher early mass and exercise late in life to stimulate muscle preservation.

Age-Related Musculoskeletal Syndromes

The most important age-related clinical syndrome associated with advancing age is osteoporosis (Chapter 251). Sarcopenia, or diminished muscle mass, is a clear predisposing factor for falls, which is the leading cause of accidental death at home in older individuals. Bone and muscle mass respond well to gravitational stress and resistance exercises, respectively, even in the oldest age ranges.

Falls are a major age-related syndrome involving neural, musculoskeletal, and cardiovascular systems. Most falls in older adults are due to a combination of several factors rather than a single event. Internal contributors to falls include sensory impairment from poor eyesight, hearing loss, and balance disturbances; diseases of the brain, including motor and sensory disorders, cognitive impairment that produces poor judgment or apraxia, and depression; cardiovascular, respiratory, and metabolic diseases; and musculoskeletal conditions, such as lower limb weakness, poor grip strength, osteoporosis, rheumatoid arthritis, osteoarthritis, and foot disorders. External causes of falls include medications. The risk of falling increases in patients who receive four or more prescription medications; drugs specifically shown to increase the risk of falling include hypnotics, muscle relaxants, antihypertensives, diuretics, and antidepressants. Environmental problems increase the risk of falls. Inside the home, risks include stairs (coming down is more hazardous than climbing up, as the first and last steps often have no railing or an unusable one); loose objects, such as furniture, cords, and rugs; poor lighting, particularly in areas with dark and light variability; poorly fitting shoes; surfaces with

glare or patterning; and lack of bathroom safety equipment. Outdoor risks include uneven pavements and surface roads made slippery from ice, water, or fallen leaves.

For a person who has fallen, the evaluation should include a detailed history of the circumstances surrounding the fall, medications, medical problems, and mobility; an examination of vision, gait, balance, and lower extremity joint function; an examination of neurologic function, including muscle strength; and an examination of the cardiovascular system. The investigations for falls and syncope (Chapters 50 and 62) are similar. Tests are needed only if the history and physical examination do not reveal the cause of falling or if they point to a particular abnormality that requires laboratory evaluation. These tests may include the following:

- Blood tests to exclude anemia, infection, and metabolic problems such as diabetes and thyroid disease
- Electrocardiogram to evaluate heart disease
- 24-Hour electrocardiogram recording or loop monitor to evaluate arrhythmias (Chapter 62)
- Echocardiogram for patients with significant heart murmurs (Chapter 55)
- Drug levels to determine whether a patient is being undertreated or overtreated with a particular drug
- If focal neurologic signs or symptoms are present, a computed tomographic scan of the brain
- If suggestive symptoms are present, a radiograph of the neck or spine to look for spinal stenosis (Chapter 407)

The risk of falls can be reduced by exercise interventions in community-dwelling elderly persons[2] and by multifactorial interventions in elderly persons in nursing facilities and hospitals.[3]

Prevention of Fractures

The prevention of fractures has three components. First, persons with lower bone densities are more likely to fracture a bone, given the same amount of trauma, than are persons with higher bone densities. Women should be assessed for osteoporosis and treated accordingly (Chapter 251). Osteoporosis often is underdiagnosed in men, and men with fractures or repeated falls should be evaluated for possible osteoporosis; however, screening strategies for elderly men have not been defined.

Fractures can be prevented if falls can be prevented. Older people who have recurrent falls should have regular exercise and balance training after their risk factors for falling are fully addressed. The optimal type, duration, and intensity of exercise are unclear, but balance training for 10 weeks or more has the best-proven benefit. Exercise must be sustained for continued benefit. Vitamin D improves muscle strength but may not reduce falls.

When someone falls, the damage may be reduced by the intrinsic padding of fat or by devices such as mechanical hip protectors. Randomized controlled trials of hip protectors to reduce fractures in nursing home patients and in ambulatory older individuals have shown mixed results in the United States. Compliance with these cumbersome devices is only 25 to 70%.

Nervous System

Brain size decreases with advancing age; after the age of 60 years, its size declines by 5 to 10%. The decrease in size is caused primarily by a decrease in the cerebral cortex. Novel adjustments to cell loss include the formation of new connections between remaining neurons. Aging is associated with a progressive decline in the synthesis of neurotransmitters and a decline in their corresponding receptors. A major functional change is slower reaction times, which may be the result of a slower nerve conduction or trans-synaptic speed.

The farsightedness of aging is caused by the diminished ability of the lens to focus on nearby objects because of its thickening and stiffening (Chapter 431). There is reduced ability to distinguish colors, particularly blue, because of yellowing of the lens. Overall transmission of light through the lens may decline by 50 to 65% between the ages of 25 and 60 years; as a result, individuals require more ambient light. Older individuals experience more glare because light scatters through the thickened lens. Older individuals also notice more floaters as the vitreous jelly becomes slightly more liquefied and mobile with advancing age. Tear production is decreased, leading to a sense of grittiness in the older eye. Overall visual acuity tends to decrease with age; by age 65 years, 40% of men and 60% of women have a visual acuity of 20/70 or worse.

Approximately 25% of individuals older than 65 years experience hearing loss with age (Chapter 436), with men affected more than women. The degeneration of neural transmission from the ear to the brain results in difficulty in identifying a voice or understanding a spoken message when there is background noise. Presbycusis results in high-frequency sound loss and more difficulty in distinguishing high-pitched consonants and voices compared with lower-pitched vowels and sounds.

Sleep patterns change with advancing age (Chapter 412). Functionally, older adults are more wakeful during the night and spend much more time in bed. The pattern of sleep characteristically changes from the fairly regular stepwise patterns of childhood and young adulthood to a more fragmented pattern, with frequent awakenings in late life.

Defined changes in brain function also occur with age, even in persons who do not meet standardized criteria for cognitive impairment. For example, the older brain does less well with divided attentional tasks, and it processes more slowly.

Age-Related Neurologic Syndromes

Age-associated memory dysfunction is common (Chapters 26 and 409), and delirium (Chapter 27) may occur, especially during illnesses. Prevention of delirium is possible with a proactive consultation intervention, which can reduce the incidence of hospital delirium by about 40 to 50%.

Sleep-disordered breathing associated with sleep apnea appears to rise in prevalence with advancing age (Chapter 100). Anatomic changes, such as tissue laxity and diseases of the nose and sinuses, may contribute to sleep-disordered breathing. Sleep apnea may have a neurologic basis either in the sleep cycling center, leading to central sleep apnea, or in neurologic control of pharyngeal tissues.

Integumentary System

Thinning of the subcutaneous tissue begins in most people in their mid-40s, independent of the degree of sun exposure or protection from injury. The epidermis and dermis adhere less tightly, making the skin feel looser and increasing its tendency to blister and to be subject to friction burns or pressure ulceration (Chapter 443). This phenomenon also leads to senile purpura (Fig. 24-1) that results from tears in small venules when the skin is bumped or abraded (Chapter 448).

Environmental exposures, including ultraviolet sunlight, wind, and smoking, help promote the development of wrinkles by damaging the subcutaneous tissues and the epidermis, especially the elastin fibers. The process of photo injury (Chapter 446) leads to slow repair, particularly of tissues of the distal forearm and lower leg. Ultraviolet light exposure also predisposes to the development of skin cancers, the most common of which is basal cell cancer, but squamous cell cancer and melanoma are also age dependent (Chapter 210). Approximately two thirds of aging individuals experience at least one skin problem, and about 40% have two underlying skin disorders.

The most profound consequence of environmental exposure and age-related changes is that wound repair rates are significantly prolonged. In individuals older than 65 years, healing takes about 50% longer compared with individuals in their 30s; complete skin healing can take 5.5 weeks instead of 3.5 weeks.

Rates of epithelial cell regeneration decrease by about 50% from maturity to 70 years of age. A similar pattern is seen in hair, which grows more slowly.

FIGURE 24-1. Senile purpura is a common and benign condition that results from impaired collagen production and capillary fragility in elderly people. In the absence of other signs of disease, no investigation is necessary. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

With advancing age, graying is variable but universal because the number of melanocytes within hair bulbs declines with age (Chapter 450). Changes in skin cell size and shape cause irregular patterning and may predispose to water-induced or environment-induced cracking.

Age-Related Integumentary Syndromes

Specific illnesses affecting the skin include basal cell cancer and rosacea (Chapters 446 to 449). Aging skin syndromes also include xerosis, thermoregulatory changes, skin thinning, and hair loss. The primary therapy for xerosis is the external application of treatments to protect and moisturize the skin (Chapter 445).

Diminished sweating poses a threat during times of high ambient and environmental temperatures or in the context of fever (Chapters 109 and 289). The absence of sweating lessens heat loss by conduction and evaporation, and it diminishes the urge to move to a more protected environment. Because few elderly individuals experience thirst, dehydration may occur quickly in these settings. Environmental protection from temperature extremes is crucial (Chapter 109).

Pressure sores are necrotic areas of muscle, subcutaneous fat, and skin as a result of compression and subsequent ischemia (Fig. 24-2). Pressure sores usually occur between underlying bone and a hard surface or a soft surface during a prolonged time. Among elderly patients in acute care hospitals, the incidence rate is 8%, and the prevalence rate is 16%. Rates are even higher in patients who are in intensive care units or who have hip fractures.

A standard mattress can generate pressures as high as 150 mm Hg, well above the 30- to 35-mm Hg continuous-pressure threshold needed to cause pressure sores. In addition to pressure injury, shear injury is important. Shear injury, which occurs when local blood vessels are stretched and separated from underlying perforating vessels, is more likely when the patient is in a sloped position or is rubbing constantly against underlying surfaces. Burning injury also can result from friction of the superficial skin layers. A complicating feature of all pressure ulcers is moisture, which leads to softening of the skin, sticking to underlying surfaces, and easy access for infection.

Individuals at higher risk include those who are immobile; those who are incontinent of bowel or bladder; and those who have compromised circulation due to hypotension, dehydration, or vascular disease. Neurologic disease, particularly peripheral neuropathy that impairs sensation, can predispose to pressure ulcers, as can any neurologic condition that causes spasticity, contractures, or poor mobility.

Preventive strategies encourage safe positioning, regular turning, and avoidance of direct pressure. Judicious use of pressure-reducing beds may lower the incidence of pressure ulcers after hip fractures. Deep foam mattresses and air suspension beds are even more effective.

When pressure sores appear, they should be photographed to establish a baseline. Nutrition should be improved, all pressure on the wound should be removed, and active vigilance should be focused to prevent additional pressure ulcers. Débridement of necrotic tissue should be considered; wet-to-dry dressings and surgical or chemical débridement are often used. Infections may require topical or systemic antibiotics. Semiocclusive and occlusive dressings also can be helpful. Most pressure ulcers heal within 6 months, but operative repair is sometimes necessary.

FIGURE 24-2. Severe sacral pressure sore, one of the serious but preventable complications of immobility. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

Clinical Pharmacology

Of all prescription medications (Chapter 28), about 30% are taken by elderly people, even though they compose only 14% of the population. Nonprescription medications are disproportionately consumed by older individuals and are increasingly implicated in drug-drug interactions.

The gastrointestinal absorption of medications generally does not change with advancing age, despite the theoretical possibility that medications requiring acidification in the stomach may be absorbed less well because of the higher frequency of atrophic gastritis and reduced gastric acid. Drug distribution changes significantly with advancing age because medications distribute to fat or muscle. As muscle mass declines with advancing age, fat increases as a proportion of total body weight. As a result, older individuals are more sensitive to the effects of water-soluble drugs (heart) and have prolonged effects from lipophilic drugs (brain).

The decline in renal function with normal aging reduces the clearance of many drugs, especially digoxin, aminoglycosides, and cimetidine. Hepatic metabolism also may decline with age. Oxidative reactions, so-called phase 1 reactions, become impaired with normal aging, whereas phase 2 reactions (conjugation and glucuronidization) are relatively spared. A clinical example is that diazepam, which requires phase 1 and phase 2 metabolism, has a prolonged half-life with advancing age, but oxazepam, which requires only phase 2 reactions to be metabolized, does not.

The overall impact of these pharmacokinetic changes is that the half-life, which is proportional to the volume of distribution divided by drug clearance, increases for many lipophilic drugs. Poorly nourished or frail elderly persons may have a low serum albumin level. The normal age-related decline in the serum albumin level is clinically insignificant. When the albumin level is less than 3 g/dL, however, drug levels have to be interpreted on the basis of their binding to albumin; albumin levels this low are associated with an increased risk of in-hospital death and longer lengths of hospital stay.

Independent of pharmacokinetic issues, elderly people are more sensitive to many medications. The brain appears to be increasingly sensitive to many compounds, including opiates, benzodiazepines, and neuroleptics. As a result, lower doses cause effects equivalent to those seen with higher doses in younger individuals. Warfarin, which acts primarily on the liver, will maintain therapeutic anticoagulation profiles at lower doses in elderly patients because the aging liver is increasingly sensitive to blockage of vitamin K–dependent systems.

Elderly people are at higher risk for nonadherence to prescribed regimens. Factors influencing nonadherence include the number of medications and their cost, inadequate education of the patient, unacceptable side effects, and complexity of the medical regimen. Individuals who take more than three prescription drugs have lower adherence. Below three medications per day, elderly individuals in general have high adherence rates. Unfortunately, no intervention has reliably improved adherence rates in elderly people.

Perhaps the most important phenomenon in multiple-drug regimens in older individuals is the progressive accumulation of anticholinergic effects, including dry mouth, constipation, poor vision, urinary retention, balance disorders, and cognitive difficulties. Anticholinergic drugs include neuroleptics, antispasmodics, antianxiety agents, antihistamines, and medications used for urinary incontinence.

An Integrated Approach

Because elderly people commonly have many medical conditions, some of which are age-related and others exacerbated by age-related conditions, a multidisciplinary approach is often useful. For example, integrated and home-based geriatric care management improve quality of care and reduce acute care utilization among high-risk community-dwelling elderly people.■ Collaborative care interventions are more effective for depression in older people than usual care and are also of high value.■ Similarly, geriatric intervention improved functional abilities and mental well-being of vulnerable older people. Physicians should become aware of such community resources that can benefit these patients.

INCONTINENCE

NEIL M. RESNICK

DEFINITION

Urinary incontinence is the involuntary leakage of urine sufficient to be a health or social problem.

EPIDEMIOLOGY

More than twice as common in women as in men, the prevalence of incontinence increases with age. But at no age does it affect the majority of individuals—even over age 85 years. Incontinence afflicts 15 to 30% of older adults living at home, one third of those in acute care settings, and half of those in nursing homes. It predisposes to perineal rashes, pressure ulcers, urinary tract infections, urosepsis, falls, and fractures, and it is associated with embarrassment, stigmatization, isolation, depression, anxiety, sexual dysfunction, and risk of institutionalization. Its cost in the United States exceeds $26 billion annually.

Despite these considerations, geriatric incontinence remains largely neglected, by patients and physicians alike. This is unfortunate because its increased prevalence with age relates more to age-associated diseases and functional impairments than to age itself. Most importantly, incontinence is usually treatable and often curable at all ages, even in frail elderly people, although the approach in older patients must be broader than that employed in younger patients.

PATHOBIOLOGY

At any age, continence depends not only on the integrity of lower urinary tract function but also on the presence of adequate mentation, mobility, motivation, and manual dexterity. Although incontinence in younger patients is rarely associated with deficits in these domains, such deficits occur commonly in older patients in whom they can cause or exacerbate incontinence or influence therapeutic approaches.

With age, bladder capacity does not change, but bladder sensation and contractility decrease. At the cellular level, detrusor smooth muscle develops a "dense band pattern" characterized by dense sarcolemmal bands with depleted caveolae. This depletion may mediate the age-related decline in bladder contractility. In addition, an incomplete dysjunction pattern characterized by scattered protrusion junctions develops and may underlie the high prevalence of involuntary bladder contractions (detrusor overactivity) in older adults of both sexes. Urethral length and sphincter strength decrease in women, whereas the prostate enlarges in most men and causes measurable obstruction in about half. The postvoid residual volume (PVR) in the bladder also increases but normally to less than 100 mL. In addition, elderly people often excrete most of their fluid intake at night, even in the absence of venous insufficiency, renal disease, heart failure, or prostatism. Coupled with an age-associated increase in sleep disorders, most older adults have one or two episodes of nocturia per night.

None of these changes causes incontinence, but all predispose to it. This predisposition, combined with the increased likelihood that an older person will encounter an additional pathologic, physiologic, or pharmacologic insult, explains the increased prevalence of incontinence with age. The implications are equally important. The onset or exacerbation of incontinence in an older person is likely to be due to precipitants that are outside the lower urinary tract and that are amenable to medical intervention. Furthermore, treatment of the precipitants alone may be sufficient to restore continence, even if there is coexisting urinary tract dysfunction. For example, a flare of hip arthritis in a woman with age-related detrusor overactivity may decrease mobility sufficiently to convert her urinary urgency into incontinence. Treatment of the arthritis, rather than the involuntary detrusor contractions, will not only restore continence but also lessen pain and improve mobility. Because of their frequency, reversibility, and association with morbidity beyond incontinence, the transient precipitant causes should be addressed first.

Causes of Transient Incontinence

Incontinence is transient in up to one third of community-dwelling elderly people and in up to half of acutely hospitalized patients. Although most transient causes are outside the lower urinary tract (Table 25-1), three points warrant emphasis. First, the risk of transient incontinence is increased if, in addition to physiologic changes of the lower urinary tract, there also are pathologic changes. Anticholinergic agents are more likely to cause overflow incontinence in individuals with a weak or obstructed bladder, whereas excess urine output is more likely to cause urge incontinence in people with detrusor overactivity or impaired mobility. Second, these transient causes may persist if left untreated and should not be dismissed merely because incontinence is long-standing. Third, identification of the most common cause is of little value because causes vary among individuals, and geriatric incontinence is rarely due to just one cause.

Causes of Established Incontinence Related to the Lower Urinary Tract

Detrusor overactivity, which also is called involuntary bladder contraction or *overactive bladder*, generally causes *urge incontinence* and is the most common type of lower urinary tract dysfunction in incontinent elderly people, accounting for about two thirds of cases. Histologically, detrusor overactivity is associated with the complete dysjunction pattern, with widening of the intercellular space, reduction of normal (intermediate) muscle cell junctions, and emergence of novel protrusion junctions and ultraclose abutments that connect cells together in chains. These connections may mediate a change in cell coupling from a mechanical to an electrical mechanism that results in involuntary bladder contraction. Other potential causes include ischemia, abnormalities in suburothelial myofibroblasts, and changes in central nervous system structural and functional control mechanisms.

At any age, detrusor overactivity is usually idiopathic, but it can be associated with a variety of other causes that may affect prognosis and management. Such conditions include an upper motor neuron lesion (Chapters 407 and 418), urethral obstruction, stress incontinence, bladder calculus, and bladder carcinoma (Chapter 203).

Detrusor overactivity exists as two subsets in elderly people: one in which contractile function is preserved and one in which it is impaired. The latter condition, termed *detrusor hyperactivity with impaired contractility*, has several implications. First, because the bladder is weak, these patients commonly develop urinary retention, which is also seen in patients with outlet obstruction and detrusor underactivity. Second, even in the absence of retention, detrusor hyperactivity with impaired contractility mimics other lower urinary tract causes of incontinence. For instance, if the involuntary detrusor contraction occurs coincident with a stress maneuver and if the weak contraction is not detected, detrusor hyperactivity with impaired contractility will be misdiagnosed as stress incontinence. Alternatively, because detrusor hyperactivity with impaired contractility may be associated with urinary urgency, frequency, weak flow rate, elevated residual urine, and bladder trabeculation, in men it may mimic prostatic obstruction. Third, anticholinergic therapy of detrusor hyperactivity with impaired contractility may result in urinary retention owing to bladder weakness, thereby requiring alternative therapeutic approaches.

Stress incontinence, which is the second most common cause of incontinence in older women and the dominant cause in middle-aged women, usually reflects urethral hypermobility plus some degree of sphincter

TABLE 25-1 CAUSES OF TRANSIENT INCONTINENCE: DIAPERS MNEMONIC

Delirium	Result of underlying illness or medication; incontinence is secondary and abates once the cause of delirium is corrected	
Infection—*symptomatic* UTI	Acute, symptomatic UTI causes incontinence, but the far more common asymptomatic bacteriuria does not	
Atrophic urethritis/vaginitis	Characterized by vaginal erosions, telangiectasia, petechiae, and friability; may cause or contribute to incontinence. Although oral estrogen may worsen incontinence, a 3- to 12-month course of topical estrogen can be useful	
Pharmaceuticals	*Drug type:*	*Potential effects on continence:*
	Sedative-hypnotics (e.g., long-acting benzodiazepines; alcohol)	Sedation, delirium, decreased mobility
	Anticholinergics (dicyclomine, disopyramide, sedating antihistamines, antipsychotics, tricyclic antidepressants, anti-Parkinson's, antidepressants)(*not* SSRIs)	Urinary retention, overflow incontinence, delirium, impaction; the antipsychotics also decrease mobility
	Opiates	Urinary retention, stool impaction, sedation, delirium
	α-Adrenergic antagonists	Relax sphincter; may induce stress incontinence in women
	α-Adrenergic agonists	Urinary retention in men (tighten sphincter, prostate)
	Calcium channel blockers, especially the dihydropyridines	Urinary retention; nocturnal diuresis due to fluid retention
	"Loop" diuretics (thiazide-like agents only rarely cause it)	Polyuria, frequency, urgency
	NSAIDs	Nocturnal diuresis due to fluid retention
	Thiazolidinediones	Nocturnal diuresis due to fluid retention
	Dopamine receptor agonists (e.g., ropinirole, pramipexole)	Nocturnal diuresis due to fluid retention
	Angiotensin-converting enzyme inhibitors	Drug-induced cough leads to stress incontinence in women
	Vincristine	Urinary retention due to neuropathy
Excess urine output	From large intake, diuretic agents (theophylline, caffeinated beverages, alcohol), and metabolic disorders (hyperglycemia, hypercalcemia); nocturnal incontinence may result from mobilization of peripheral edema (CHF, venous insufficiency)	
Restricted mobility	Often results from overlooked, correctable conditions such as arthritis, pain, foot problems, postprandial hypotension	
Stool impaction	May cause both fecal and urinary incontinence that remit with disimpaction	

CHF = congestive heart failure; NSAIDs = nonsteroidal anti-inflammatory drugs; SSRI = selective serotonin reuptake inhibitor; UTI = urinary tract infection.
Adapted from Resnick NM, Tadic SD, Yalla SV. Geriatric incontinence and voiding dysfunction. In: Wein AJ, Novick AC, Partin AW, et al, eds. *Campbell-Walsh Urology*, 10th ed. St. Louis: Elsevier; 2010.

weakness. Stress incontinence is rare in men but can result from sphincter damage following radical but not transurethral prostatectomy.

Urethral obstruction is the second most common cause of established incontinence in older men, although most obstructed men are not incontinent. When obstruction is associated with incontinence, it usually presents as urge incontinence owing to the associated detrusor overactivity; overflow incontinence is uncommon. Outlet obstruction is rare in women but may result from a bladder neck suspension or from urethral kinking associated with a large cystocele.

Detrusor underactivity is usually idiopathic. When it causes incontinence, it is associated with overflow incontinence (<10% of incontinence).

Damage to lower urinary tract innervation can cause several types of dysfunction. A brain lesion may cause detrusor overactivity. A spinal cord lesion (Chapters 195 and 407) above the sacral level can cause both detrusor overactivity and detrusor-sphincter dyssynergia, a condition in which the sphincter contracts rather than relaxes during detrusor contraction; the result can be severe outlet obstruction and hydronephrosis. A spinal cord lesion below the sacral level can cause detrusor underactivity, sphincter weakness, or both. Peripheral and autonomic nerve damage can cause still additional problems. Because *neurogenic bladder* is such a nonspecific term, it is preferable to refer to the dysfunction that it causes.

Causes of Incontinence Unrelated to the Lower Urinary Tract (Functional Incontinence)

"Functional" incontinence, which is often cited as a distinct type of geriatric incontinence and attributed to deficits of cognition and mobility, implies that urinary tract function is normal. However, normal urinary tract function is the exception, even in continent elderly people, and is rarely observed in incontinent elderly people. Incontinence is not inevitable, even with dementia or immobility. Among the most severely demented institutionalized residents, nearly 20% are continent; among those who can transfer from a bed to a chair, nearly half are continent. Functionally impaired individuals also are the most likely to suffer from factors that cause transient incontinence, and a diagnosis of functional incontinence may result in failure to detect these reversible causes. Finally, if functionally impaired individuals also have urethral obstruction or stress incontinence, they may benefit from targeted therapy. Nonetheless, functional impairment often contributes to incontinence, and addressing its causes and those of transient incontinence may ameliorate incontinence sufficiently to obviate the need for further investigation.

CLINICAL MANIFESTATIONS

The manifestations of transient incontinence depend on the underlying condition. For established incontinence, detrusor overactivity usually manifests as *urge incontinence,* characterized by leakage that follows the abrupt onset or intensification of a desire to void, leakage of a moderate to large amount, urinary frequency (>8 voids/day), nocturia, and nocturnal incontinence. However, some patients with detrusor overactivity may present without the urge component. *Stress incontinence* causes leakage that coincides with both the onset and cessation of a cough or other cause of increased abdominal pressure; nocturnal leakage is rare. Some patients report both types of incontinence, or *mixed incontinence*, but it is useful to determine which component is the most bothersome. Occasionally, patients present with incontinence that is more difficult to characterize clinically without further testing.

DIAGNOSIS

In addition to a targeted clinical evaluation (Table 25-2), a bladder diary can provide diagnostic clues and guide therapy (Fig. 25-1). For example, incontinence occurring only between 8 AM and noon may be caused by a morning loop diuretic. Incontinence that occurs at night in a demented man with heart failure, but not during a 4-hour nap in his wheelchair, is likely due to nocturnal diuresis associated with his heart failure and not to dementia, impaired mobility, or prostatic obstruction. A woman with volume-dependent stress incontinence may leak only on the way to void after a full night's sleep, when her bladder contains more than 400 mL—more than it ever does during her continent waking hours.

Because urinary retention is difficult to detect by examination and can affect diagnosis and therapy, the PVR volume should be determined routinely, except possibly in middle-aged women with a classic presentation of stress incontinence. Urodynamic testing is generally unnecessary unless diagnostic certainty is required, such as before surgical repair or if there is evidence of a serious underlying cause of the incontinence, such as a brain or spinal cord lesion, carcinoma of the bladder or prostate, hydronephrosis, or bladder calculus. Urodynamic evaluation comprises a battery of tests designed to assess the lower urinary tract during the filling and voiding phases of micturition. The selection among tests depends on the clinical setting and question to be answered; for instance, measuring detrusor pressure and urine flow during voiding can determine whether urethral obstruction is present, whereas monitoring bladder and urethral pressures during the filling phase and with coughing may be helpful for patients with an atypical presentation of mixed incontinence.

TABLE 25-2 CLINICAL EVALUATION OF THE INCONTINENT PATIENT

HISTORY

Type (urge, stress, overflow, or mixed)
Incontinence frequency, severity, duration
Pattern (diurnal, nocturnal, or both; also, e.g., after taking medications)
Associated symptoms (straining to void, incomplete emptying, dysuria, hematuria, suprapubic/perineal discomfort)
Alteration in bowel habit/sexual function (because of proximity to the bladder and shared innervation)
Other relevant factors (cancer, acute illness, neurologic disease, pelvic or lower urinary tract surgery/radiation therapy)
Medications, including nonprescription agents (see Table 25-1)
Brief assessment of cognitive and physical function

PHYSICAL EXAMINATION

Identify other relevant medical conditions (e.g., congestive heart failure, peripheral edema)
If stress incontinence suspected, determine whether leakage *coincides* with the onset *and* cessation of a single, forceful cough
Palpate for bladder distention after voiding
Pelvic examination to detect atrophic vaginitis, pelvic muscle laxity, pelvic mass
Rectal examination (skin irritation, resting tone and voluntary control of anal sphincter, prostate nodule; fecal impaction (*note:* prostate size correlates poorly with presence of urethral obstruction)
Neurologic examination (mental status and elemental examination, including sacral reflexes and perineal sensation)

INITIAL INVESTIGATION

Bladder diary (see Fig. 25-1)
Metabolic survey (electrolytes, calcium, glucose, and urea nitrogen as appropriate)
Measure postvoid residual (PVR) volume, by portable ultrasound if available
Urinalysis to detect sterile hematuria or infection; culture if new-onset or worsening incontinence
Renal ultrasound to detect hydronephrosis in men whose PVR urine exceeds about 200 mL
Urine cytology for patients with hematuria, pain, or unexplained new-onset or worsening incontinence
Uroflowmetry for men in whom urethral obstruction is suspected
Cystoscopy for patients with hematuria, suspicion of lower urinary tract pathology (e.g., bladder fistula, stone, or tumor; urethral diverticulum), or need for lower urinary tract surgery

Adapted from Resnick NM, Yalla SV. Management of urinary incontinence in the elderly. *N Engl J Med.* 1985;313:800-805.

Date	Time	Volume Voided (mL)	Are You Wet or Dry?	Approximate Volume of Incontinence	Comments
4/5	3:40 pm	240	Wet	Slight	
	6:05 pm	210	Dry		
	8:15 pm	150	Dry		Running water
	10:20 pm	150	Wet	15 mL	Bowel movement
	10:30 pm	30	Dry

	11:20 am	200	Dry		
	12:50 pm	180	Dry		
	1:40 pm	240	Dry		
	3:35 pm	160	Dry		
	6:00 pm	170	Dry		
	8:20 pm	215	Wet	Slight	Running water
	10:25 pm	130	Dry		

FIGURE 25-1. Sample bladder diary. Bladder diary of an incontinent 75-year-old man. Urodynamic evaluation excluded urethral obstruction and confirmed a diagnosis of detrusor hyperactivity with impaired contractility (detrusor hyperactivity with impaired contractility). Note the 24-hour urine output of nearly 3 liters due to the belief that drinking 10 glasses of fluid per day was "good for my health." (He did not mention this until queried about the voiding record.) Given the typical voided volume of 150 to 250 mL and a measured postvoid residual of 150 mL, excess fluid intake was overwhelming his usual bladder capacity of 400 mL (150 + 250 mL). Although involuntary bladder contractions were present, the easily reversible volume component of the problem, combined with the risk of precipitating urinary retention with an anticholinergic agent, prompted treatment with volume restriction alone. After daily urinary output dropped to 1500 mL, frequency abated, and incontinence resolved. (Adapted from DuBeau CE, Resnick NM. Evaluation of the causes and severity of geriatric incontinence: a critical appraisal. *Urol Clin North Am.* 1991;18:243-256.)

TREATMENT

Optimal therapy requires a multifactorial approach (Table 25-3), including treatment of transient causes, underlying medical conditions, functional impairments, and the urinary tract abnormality itself. Although pads and diapers have a role, they remain an adjunct to more specific therapy.

Behavioral Therapy

Behavioral therapy includes education, self-monitoring with a bladder diary, adjustment of fluid intake, weight loss for overweight women with stress incontinence,[4] use of aids (e.g., a bedside urinal), and various types of bladder retraining and urethral sphincter exercises (e.g., progressively increasing voiding intervals, strategies to cope with urgency, and pelvic muscle exercises).[1-3] The efficacy of behavioral therapy is equivalent to pharmacotherapy for urge incontinence and is superior to drugs for stress incontinence.[2,5] Moreover, combining behavioral and pharmacologic therapy may prove more beneficial than either treatment alone, especially for urge incontinence, because neither therapy generally abolishes involuntary bladder contractions. For institutionalized patients who are cognitively impaired but can state their name and are partly mobile, regular daytime reminders to void ("prompted voiding") have proved effective for daytime incontinence; pads and diapers are appropriate for the others.[4]

Pharmacotherapy

Currently approved drugs have generally proved ineffective for stress incontinence and overflow incontinence, but several bladder relaxants are available for urge incontinence (see Table 25-3). Each has proved superior to placebo in well-conducted trials, and most have also proved effective in trials targeting older patients.[2,5] All have antimuscarinic properties, such as dry mouth, constipation, visual blurring, and occasional confusion. Yet each is well tolerated even in cognitively impaired elderly patients when prescribed properly, although cognitive status should be monitored. These drugs also can be well tolerated in patients taking cholinesterase inhibitors. The choice among drugs often hinges on other considerations. For instance, immediate-release oxybutynin has the quickest onset of action, making it an inexpensive and effective choice for patients who need excellent control at predictable times. The other drugs, although more expensive, can be used less often and can be better tolerated for daily use.

Regardless of the agent selected, the key is to begin with a low dose and increase it slowly, realizing that the full benefit is generally not apparent for

TABLE 25-3 STEPWISE APPROACH TO TREATMENT OF URINARY INCONTINENCE*

CONDITION	CLINICAL TYPE OF INCONTINENCE†	TREATMENT
Detrusor overactivity with normal contractility	Urge	1. Bladder retraining or prompted voiding regimens 2. ± Bladder relaxant medication if needed and not contraindicated (see drug list below) 3. Indwelling catheterization alone is often unhelpful because detrusor spasms often increase, leading to leakage around the catheter 4. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization‡
Detrusor hyperactivity with impaired contractility	Urge§	1. If bladder empties adequately, behavioral methods (as above) ± bladder relaxant medication (low doses; especially feasible if sphincter incompetence coexists) 2. If residual urine >150 mL, augmented voiding techniques¶ or intermittent catheterization (± bladder relaxant medication). If neither feasible, undergarment or indwelling catheter‡ 3. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization‡
Stress incontinence	Stress	1. Conservative methods (weight loss if obese; treatment of cough or atrophic vaginitis; physical maneuvers to prevent leakage [e.g., tighten pelvic muscles before cough, cross legs]; occasionally, use of tampon or pessary is helpful) 2. If leakage threshold ≥150 mL identified, adjust fluid excretion and voiding intervals appropriately 3. Pelvic muscle exercises ± biofeedback/weighted intravaginal cones; must continue indefinitely 4. Surgery (sling, artificial sphincter, periurethral bulking injections)
Urethral obstruction	Urge/overflow‖	1. Conservative methods (including adjustment of fluid excretion, bladder retraining/prompted voiding) if hydronephrosis, recurrent symptomatic UTI, and hematuria have been excluded 2. α-Adrenergic antagonist 3. Also consider adding a bladder relaxant if detrusor overactivity coexists, PVR is small, and surgery not desired/feasible; *monitor PVR!* 4. Finasteride, if not contraindicated and the patient either prefers it or is not a surgical candidate 5. Surgery (incision, prostatectomy) is an effective alternative before or after these steps
Underactive detrusor	Overflow	1. Decompress for at least several days (the larger the PVR, the longer should be the decompression [up to a month]) and then perform a voiding trial 2. Exclude urethral obstruction if this has not already been done 3. If cannot void or PVR remains large, try augmented voiding techniques¶ ± α-adrenergic antagonist, but only if some voiding possible; bethanechol *rarely* useful 4. If fails, or voiding is not possible, intermittent or indwelling catheterization‡

*These treatments should be initiated only after adequate toilet access has been ensured, contributing conditions have been treated (e.g., atrophic vaginitis, UTI, fecal impaction, heart failure), fluid management has been optimized, and unnecessary or exacerbating medications have been addressed. For additional details, see text.
†*Urge:* leakage in the absence of stress maneuvers and urinary retention, usually preceded by *abrupt* onset or intensification of the need to void; *stress:* leakage that coincides *instantaneously* with stress maneuvers, in the absence of urinary retention or detrusor contraction; *overflow:* frequent leakage of small amounts associated with urinary retention.
‡UTI prophylaxis can be used for recurrent symptomatic UTIs, but only if catheter is not indwelling.
§May also mimic stress or overflow incontinence.
‖Also can cause postvoid "dribbling" alone, which is treated conservatively (e.g., by sitting to void and allowing more time, "double voiding," and in men by gently "milking" the urethra after voiding).
¶Augmented voiding techniques include Credé (application of suprapubic pressure) and Valsalva (straining) maneuvers, and double voiding. They should be performed only *after* voiding has begun.
Anticholinergic bladder relaxant agents for urge incontinence:
Oxybutynin IR, 7.5-20 mg daily (2.5-5 mg tid-qid); oxybutynin XL, 5-30 mg once daily; oxybutynin patch twice weekly; oxybutynin 10% gel (1 g topically per day)
Tolterodine, 2 mg twice daily; tolterodine LA, 4 mg once daily
Darifenacin, 7.5-15 mg once daily
Solifenacin, 5-10 mg once daily
Trospium, 20 mg daily to twice daily; XL now available
Fesoterodine, 4-8 mg once daily
PVR = postvoid residual; UTI = urinary tract infection.

about 2 months and that side effects may offset the benefit. With such titration, urge incontinence can be controlled in about one third of patients and substantially improved in another one third.

Surgical Procedures

Surgery for stress incontinence has proved effective for women of all ages, including elderly women, and is relatively durable. Periurethral bulking injections can help frail women or those with mild stress incontinence, but it does not generally restore continence. However, urethral sling and midurethral tape suspension procedures can cure most women for at least 5 years.[1] For women with more complex stress incontinence and for men with stress incontinence more than a year after radical prostatectomy, an artificial sphincter has proved effective and relatively durable. Experience with the "male sling" is still limited.

Surgical interventions for urge incontinence, including neuromodulation, tibial nerve stimulation, and injections of botulinum toxin are successful in selected situations. However, they have not been studied adequately in elderly people, and the limited preliminary data suggest that older patients may not fare as well as younger ones.

PREVENTION

There are scant data regarding the prevention of incontinence, but one randomized trial of an educational and behavioral modification program for women older than 55 years found that it reduced the risk of incontinence for a year.[6] A secondary analysis of the Diabetes Prevention Program found that, at the end of 3 years, an intensive lifestyle intervention was associated with reduced risk of self-reported incontinence, with most of the benefit explained by weight loss and a reduced risk of stress incontinence.[7]

PROGNOSIS

Limited data suggest that incontinence progresses in about one third of patients and remits in about 10 to 15%, although it is unclear how much of the remission reflects intervention or improvement in functional or medical status.

NEUROPSYCHIATRIC ASPECTS OF AGING

SHARON K. INOUYE

DEFINITION

The process of aging produces important physiologic changes in the central nervous system (Table 26-1), including neuroanatomic, neurotransmitter, and neurophysiologic changes. These processes result in age-related symptoms and manifestations (Table 26-2) for many older persons. These physiologic changes develop at dramatically variable rates among older persons, however, and the decline may be modified by factors such as diet, exercise, environment, lifestyle, genetic predisposition, disability, disease, and side effects of drugs. These changes can result in the common age-related symptoms of benign senescence, slowed reaction time, postural hypotension, vertigo or giddiness, presbyopia, presbycusis, stiffened gait, and sleep difficulties. In the absence of disease, these physiologic changes usually result in relatively modest symptoms and little restriction in activities of daily living. These changes decrease physiologic reserve, however, and increase the susceptibility to challenges posed by disease-related, pharmacologic, and environmental stressors.

EPIDEMIOLOGY

Neuropsychiatric disorders, the leading cause of disability in older persons, account for nearly 50% of functional incapacity. Severe neuropsychiatric conditions have been estimated to occur in 15 to 25% of older adults worldwide. These conditions are due to diseases that increase with age but are not part of the normal aging process. Alzheimer's disease and related dementias occur in approximately 10% of adults aged 65 years and older and in 40% of those older than 85 years (Chapter 409). Delirium occurs in 5 to 10% of all persons older than 65 years and in up to 80% of older persons during hospitalizations for acute illnesses (Chapter 27). Severe depression (Chapter 404) occurs in approximately 5% of older adults, with 15% having significant depressive symptoms. Anxiety disorders occur in 10% of older adults. Older individuals are also subject to substantial morbidity and functional disability from cerebrovascular disease (Chapters 413 through 415), Parkinson's disease (Chapter 416), peripheral neuropathies (Chapter 428), degenerative myelopathies (Chapters 407 and 430), spinal stenosis and disc disease (Chapter 407), seizure disorders (Chapter 410), sleep apnea (Chapter 100), visual disturbances (Chapter 431), falls (Chapter 24), incontinence (Chapter 25), and impotence (Chapter 242).

TABLE 26-1 AGE-RELATED PHYSIOLOGIC CHANGES IN THE CENTRAL NERVOUS SYSTEM

Neuroanatomic changes
Brain atrophy
Decreased neuron counts
Increased neuritic plaques
Increased lipofuscin and melanin
Neurotransmitter changes
Decline in cholinergic transmission
Decreased dopaminergic synthesis
Decreased catecholamine synthesis
Neurophysiologic changes
Decreased cerebral blood flow
Electrophysiologic changes (slowing of alpha rhythm, increased latencies in evoked responses)

DIAGNOSIS

To diagnose these conditions, physicians must understand and perform a mental status examination and an assessment of functional capacity and know the uses and side effects of psychoactive drugs in geriatric patients.

Mental Status Examination

In addition to a detailed neurologic examination, evaluation of neuropsychiatric disturbances in older persons requires a careful mental status examination, including an assessment of mood, affect, and cognition. Brief screening tests are available to evaluate these domains and to assist in the detection of potential problems requiring further evaluation and treatment. For depression screening, scores of 6 or more on the 15-item short-form Geriatric Depression Scale (Table 26-3) indicate substantial depressive symptoms requiring further evaluation. Alternative depression screening instruments include the Center for Epidemiologic Studies Depression Scale (CES-D). For cognitively impaired patients, observer-rated depression scales, such as the Hamilton Depression Scale or Cornell Scale, are recommended.

TABLE 26-2 NEUROPSYCHIATRIC MANIFESTATIONS OF AGE-RELATED PHYSIOLOGIC CHANGES

SYSTEM	MANIFESTATION
Cognition	Forgetfulness Processing speed declines throughout adult life Neuropsychological declines: selective attention, verbal fluency, retrieval, complex visual perception, logical analysis
Reflexes	Stretch reflexes lose sensitivity Decreased or absent ankle reflexes Decreased autonomic and righting reflexes, postural instability
Sensory	Presbycusis (high-frequency hearing loss), tinnitus Deterioration of vestibular system, vertigo Presbyopia (decreased lens elasticity) Slowed pupil reactivity, decreased upgaze Olfactory system deterioration Decreased vibratory sensation
Gait and balance	Gait stiffer, slowed, forward flexed Increased body sway and mild unsteadiness
Sleep	Decreased sleep efficiency, fatigue Increased awakenings, insomnia Decrease in sleep stages 3 and 4 Sleep duration more variable, more naps

TABLE 26-3 GERIATRIC DEPRESSION SCALE—SHORT FORM

1. Are you basically satisfied with your life?	yes/**NO**
2. Have you dropped many of your activities and interests?	**YES**/no
3. Do you feel that your life is empty?	**YES**/no
4. Do you often get bored?	**YES**/no
5. Are you in good spirits most of the time?	yes/**NO**
6. Are you afraid that something bad is going to happen to you?	**YES**/no
7. Do you feel happy most of the time?	yes/**NO**
8. Do you feel helpless?	**YES**/no
9. Do you prefer to stay home rather than going out and doing new things?	**YES**/no
10. Do you feel you have more problems with memory than most?	**YES**/no
11. Do you think it is wonderful to be alive now?	yes/**NO**
12. Do you feel pretty worthless the way you are now?	**YES**/no
13. Do you feel full of energy?	yes/**NO**
14. Do you feel that your situation is hopeless?	**YES**/no
15. Do you think that most people are better off than you are?	**YES**/no

Scoring: Answers indicating depression are highlighted; six or more highlighted answers indicate depressive symptoms.
Modified from Yesavage J, Brink T, Rowe T, et al. Development and validation of a geriatric depression screening scale: a preliminary report. *J Psychiatr Res.* 1983;17:37-49.

FIGURE 26-1. Montreal Cognitive Assessment (MOCA).

Early cognitive deficits can easily be missed during conversation because intellectual impairment can be masked with intact social skills. Given the high frequency of cognitive impairment, formal cognitive screening is recommended for all older persons. Ideally, cognitive testing should evaluate at least the general domains of attention, orientation, language, memory, visuospatial ability, and conceptualization. To exclude delirium, attention should be assessed first by asking the patient to perform a task, such as repeating five digits or reciting the months backward; the remainder of cognitive testing would not be useful in an inattentive patient. For further cognitive testing, many brief, practical screening instruments are available. Historically, the most widely used instrument has been the Mini-Mental State Examination, a 19-item, 30-point scale that can be completed in 10 minutes. This copyrighted instrument now requires a per-use fee if the official version is used. A useful, brief alternative instrument is the Mini-Cog test, which can be completed in 2 to 4 minutes (Table 26-4); scores <3 suggest cognitive impairment. More detailed testing can be conducted with the Montreal Cognitive Assessment (Figure 26-1), which requires 10 to 15 minutes; scores less than 26 indicate cognitive impairment. Questions to evaluate judgment and problem-solving ability in hypothetical situations, such as in a fire or when driving, can provide crucial insight into the patient's ability to function safely and independently.

Functional Assessment

Functional impairment, defined as difficulty in performing daily activities, is common among elderly persons. Although it is not routinely evaluated in the standard medical assessment, determination of the patient's degree of functional incapacity based on medical and neuropsychiatric conditions is crucial to understanding the burden of disease and its impact on the individual's daily life. The important relationship between functional status and health in older persons is reflected by the finding that functional measures are stronger predictors of mortality after hospitalization than are admitting diagnoses. Functional measures strongly predict other important hospital outcomes in the elderly, such as length of stay, functional status at discharge, future care needs, caregiver burden, risk for institutionalization, and long-term prognosis. Functional independence is critical if patients are to remain living independently in the community, and functional decline represents a leading risk factor for nursing home placement.

The functional assessment should include an assessment of the patient's ability to perform basic self-care activities of daily living and instrumental activities of daily living, the higher level activities needed for independent living. Activities of daily living include basic self-care skills such as feeding, grooming, bathing, dressing, toileting, transferring, and walking. Instrumental activities of daily living are more complex tasks, including shopping, preparing meals, managing finances, housekeeping, using the telephone, taking medications, and driving or using public transportation. The functional assessment is conducted with the patient or the family, and the questions ascertain whether the patient can perform these activities independently. Other related domains that should be assessed include vision, hearing, continence, nutritional status, safety, falls, living situation, social support, and socioeconomic status.

The onset of acute cognitive or functional decline is often the first and sometimes the only sign of serious acute illness in older persons, and it warrants immediate medical attention. Similarly, the onset or worsening of related conditions, such as delirium, falls, incontinence, depression, frailty, or failure to thrive, heralds the need for prompt medical evaluation.

TABLE 26-4 MINI-COG TEST

1. Instruct the patient to listen carefully to and remember 3 unrelated words and then to repeat the words: BANANA, SUNRISE, CHAIR.
2. Instruct the patient to draw the face of a clock, either on a blank sheet of paper or on a sheet with a large circle already drawn on the page. After the patient puts the numbers on the clock face, ask him or her to draw the hands of the clock to read a specific time, such as 11:10. These instructions can be repeated, but no additional instructions should be given. Allow up to 3 minutes to complete the clock drawing.
3. Ask the patient to repeat the 3 previously presented words.
4. Give 1 point for each correct word and 2 points for a correctly drawn clock. Scores <3 suggest cognitive impairment.

TREATMENT

Psychoactive Effects of Drugs in Older Patients

Adverse Drug Events in the Elderly

Iatrogenic complications occur in 29 to 38% of older hospitalized patients, with a three- to five-fold increased risk in older compared with younger patients. Adverse drug events, the most common type of iatrogenic complication, account for 20 to 40% of all complications. The elderly are particularly vulnerable to adverse drug reactions because of multiple-drug regimens, multiple chronic diseases, relative renal and hepatic insufficiency, decreased physiologic reserve, and altered drug metabolism with aging. Inappropriate drug use has been reported in about 40% of hospitalized older patients, with more than one quarter of these patients having absolute contraindications to the drug and the others being given a drug that was unnecessary. Because 50% of adverse drug events occur in patients receiving inappropriate drugs, the potential for reducing these adverse events is substantial.

Drugs with Psychoactive Effects

Nearly every class of drug has the potential to cause mental status changes in a vulnerable patient, but specific drugs are commonly implicated (Table 26-5) and should be used with caution in older patients. Many cases of delirium or cognitive decline in older patients may be preventable through avoidance, substitution, or dose reduction of these psychoactive drugs. Long-acting benzodiazepines (e.g., flurazepam, diazepam) are particularly problematic medications for the elderly and should be avoided whenever possible. If nonpharmacologic approaches to the management of insomnia are unsuccessful, short-term use of an intermediate-acting benzodiazepine without active metabolites (e.g., lorazepam 0.5 mg, half-life of 10 to 15 hours) is recommended. Drugs with anticholinergic effects (e.g., antihistamines, antidepressants, neuroleptics, antispasmodics) produce a panoply of poorly tolerated side effects in older patients, including delirium, postural hypotension, urinary retention, constipation, and dry mouth. Of the narcotics, meperidine causes

TABLE 26-5 DRUGS WITH PSYCHOACTIVE EFFECTS

Sedative-hypnotics
Benzodiazepines (especially flurazepam, diazepam)
Barbiturates
Sleeping medications (chloral hydrate)
Narcotics (especially meperidine)
Anticholinergics
Antihistamines (diphenhydramine, hydroxyzine)
Antispasmodics (belladonna, Lomotil)
Heterocyclic antidepressants (amitriptyline, imipramine, doxepin)
Neuroleptics (chlorpromazine, haloperidol, thioridazine)
Antiparkinson drugs (benztropine, trihexyphenidyl)
Atropine, scopolamine
Cardiac drugs
Digitalis glycosides
Antiarrhythmics (quinidine, procainamide, lidocaine)
Antihypertensives (β-blockers, methyldopa)
Gastrointestinal drugs
H_2-antagonists (cimetidine, ranitidine, famotidine, nizatidine)
Proton pump inhibitors (esomeprazole, lansoprazole, omeprazole, pantoprozole)
Metoclopramide (Reglan)
Miscellaneous drugs
Nonsteroidal anti-inflammatory drugs
Corticosteroids
Anticonvulsants
Levodopa
Lithium
Over-the-counter drugs
Cold and sinus preparations (antihistamines, pseudoephedrine)
Sleep aids (diphenhydramine, alcohol-containing elixirs)
Stay Awake (caffeine)
Nausea, gastrointestinal relief (Donnagel, meclizine, H_2-antagonists, loperamide)

delirium more frequently than other agents because of an active metabolite, normeperidine. Cardiac drugs, such as digitalis and antiarrhythmic agents, have prolonged half-lives, narrowed therapeutic windows, and decreased protein binding in older patients. The clinician should be aware that toxicity with these agents (e.g., digoxin) can occur even at therapeutic drug levels. The H_2-receptor antagonists (e.g., cimetidine, ranitidine, famotidine, nizatidine) are among the most common causes of drug-induced delirium in the elderly because of their frequent use; clinicians should strongly consider the use of less toxic alternatives (e.g., sucralfate, antacids) or dosage reductions for older patients, especially when the medication is being used for prophylaxis rather than treatment of active disease. Proton pump inhibitors have been associated with delirium in case reports; however, the overall rate of this adverse effect has not been systematically determined. The Beers list, which is updated regularly, includes drugs that are potentially inappropriate for the elderly and drugs associated with high rates of adverse events in the elderly, including mental status changes and falls.

Psychoactive drugs account for nearly 50% of preventable adverse drug events, often in patients who have been prescribed three or more psychoactive drugs, frequently at inappropriately high doses in the elderly. Delirium and cognitive impairment are the most frequent adverse outcomes of psychoactive drugs. The use of any psychoactive drug is associated with a 4-fold increased risk of delirium or cognitive decline, but the outcomes of these conditions depend on the type or class of drug administered and the total number of drugs received. Sedative-hypnotic drugs are associated with a 3- to 12-fold increased risk for delirium or cognitive decline, narcotics are associated with a 2- to 3-fold increased risk, and anticholinergic drugs are associated with a 5- to 12-fold increased risk. Each drug carries its own individual risk for adverse outcomes, and when multiple drugs are used, the overall risk is compounded by the heightened potential for drug-drug interactions. If more than three drugs are added in a 24-hour period, the risk of delirium increases 4-fold. Similarly, the risk of cognitive decline increases directly with the number of drugs prescribed, from a 3-fold increased risk with two or three drugs to a 14-fold increased risk with six or more drugs.

Principles of Drug Therapy in the Elderly

Physicians always should consider whether nonpharmacologic approaches (Chapter 38) may be used as alternatives to medications in older persons. Relaxation techniques, massage, and music are highly effective for the treatment of insomnia and anxiety; localized pain can often be managed effectively with local measures such as injection, heat, ultrasound, and transcutaneous electrical stimulation.

TABLE 26-6 GUIDELINES FOR DRUG THERAPY IN THE ELDERLY

GENERAL PRINCIPLES
Remember that the elderly are highly sensitive to the psychoactive effects of all drugs.
Know the pharmacology of the drugs you prescribe. Know a few drugs well.
RECOMMENDED APPROACH
Use nonpharmacologic approaches whenever possible.
Avoid *routine* use of "as needed" drugs for sleep, anxiety, pain.
Choose the drug with the least toxic potential.
Substitute less toxic alternatives whenever possible (antacid or sucralfate for an H_2-blocker or proton pump inhibitors, metamucil or kaopectate for imodium, or Lomotil, scheduled acetaminophen regimen for pain management).
Reduce the dosage.
"Start low and go slow."
Start with 25-50% of the standard dose of psychoactive drugs in the elderly.
Titrate the drug slowly.
Set realistic end points: titrate to improvement, not elimination of symptoms.
Keep the regimen simple.
Regularly reassess the medication list. Have the patient bring in all bottles and review what is being taken.
Re-evaluate long-time drug use because the patient is changing.
Review over-the-counter medication use.

When drug therapy is required in the elderly, physicians should choose the drug with the least toxic potential and emphasize drugs that have been well tested in older populations (Table 26-6). It is often wise to start with 25 to 50% of the standard adult dosage for any psychoactive drug and increase the dose slowly. Drug regimens should be kept simple, with the fewest drugs and the fewest number of pills possible. Most important, the medication list should be reassessed frequently. Systematic interventions involving geriatricians, clinical pharmacists, and computer-based systems can significantly reduce the frequency of adverse drug reactions in older persons.■

Even long-standing medications should be reevaluated because the patient is changing with age and illness. Long-term use does not justify continued use. The physician should review with the patient all prescribed and over-the-counter medications on a regular basis, preferably by having the patient bring in all medication bottles and indicate how each is being taken. Patients frequently underestimate the toxic potential of over-the-counter medications and herbal remedies, and they may be using a variety of such agents that could potentiate the side effects or directly counteract the desired effects of prescription medications (Chapter 28). For example, high-risk over-the-counter medications for older persons include nonsteroidal anti-inflammatory agents, H_2-blockers, and antihistamines. In addition, herbal remedies such as gingko biloba may interact with warfarin to cause bleeding; others (such as kava kava and Chinese herbal preparations) are associated with the risk of hepatotoxicity.

FUTURE DIRECTIONS

Screening methods for cognitive and functional decline should be used for high-risk older persons. An important goal for the future is to incorporate these screening and interventional measures into the routine care of all older persons in physicians' offices, clinics, hospitals, nursing homes, and other settings.

DELIRIUM OR ACUTE MENTAL STATUS CHANGE IN THE OLDER PATIENT

SHARON K. INOUYE

Mental status change, one of the most common presenting symptoms in acutely ill elders, is estimated to account for 30% of emergency evaluations among older patients. Mental status often serves as a barometer of the underlying health of an elderly patient and is commonly the only symptom of serious underlying disease. A broad range of medical, neurologic, and psychiatric conditions can lead to mental status changes (Chapters 404 and 409). A systematic approach aids in the evaluation of suspected mental status change in an older patient (Fig. 27-1).

The first step in evaluating suspected altered mental status in an older patient is to obtain a detailed history from a reliable informant to establish the patient's baseline level of cognitive function and the clinical course of any cognitive changes. Chronic changes (those occurring over months to years) most likely represent an underlying dementing illness and should be evaluated accordingly (Chapter 409). Acute changes (those occurring over days to weeks)—even if superimposed on an underlying dementia—should be evaluated by a detailed cognitive assessment to determine whether delirium is present. If features of delirium (e.g., inattention, disorganized thinking, altered level of consciousness, fluctuating symptoms) are not present, further evaluation for depression, acute nonorganic psychotic disorders, or other psychiatric conditions is indicated.

DELIRIUM

Delirium, a clinical syndrome characterized as an acute disorder of attention and cognitive function, is the most frequent complication of hospitalization for elders and is a potentially devastating problem. Delirium is often unrecognized despite sensitive methods for its detection, and its complications may be preventable.

DEFINITION

The definition of and diagnostic criteria for delirium are evolving. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (text revision) has been used widely (Table 27-1), but the criteria in this manual were based on expert consensus, and their diagnostic sensitivity and specificity have not been determined. The Confusion Assessment Method (CAM) provides a simple, operationalized diagnostic algorithm. In studies of more than 1000 subjects, it had a sensitivity of 94%, a specificity of 89%, and a high interrater reliability.

EPIDEMIOLOGY

In persons older than 65 years, the prevalence of delirium at hospital admission is 13 to 60%. Delirium develops in 6 to 56% of patients during hospitalization. Higher rates are found when frequent surveillance is performed in older, surgical, and intensive care populations. Delirium occurs in 15 to 74% of postoperative patients, 60 to 80% of patients in medical intensive care units, up to 60% of nursing home patients, and at least 80% of patients at the end of life.

The hospital mortality rates for delirium are 25 to 33%—as high as those associated with acute myocardial infarction and sepsis. The problem of delirium in hospitalized elderly patients has assumed particular prominence because patients aged 65 years and older currently account for more than 50% of all inpatient days of hospital care. Based on U.S. vital health statistics, delirium complicates hospital stays for at least 20% of the 12.5 million older persons hospitalized each year and increases hospital costs by more than $2500 per patient, amounting to more than $6.9 billion (2004 U.S. dollars) of Medicare expenditures yearly. Substantial additional costs are incurred after hospital discharge because of the increased need for rehabilitation services, nursing home placement, home care, and rehospitalization. Health care costs associated with delirium range from $38 billion to $152 billion per year. These extrapolations highlight the extensive economic and health policy implications of delirium.

TABLE 27-1 DIAGNOSTIC CRITERIA FOR DELIRIUM

DSM-IV TR DIAGNOSTIC CRITERIA

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention
B. A change in cognition (e.g., memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia
C. The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day
D. Evidence from the history, physical examination, or laboratory findings indicates that the disturbance is caused by the direct physiologic consequences of a general medical condition

CAM DIAGNOSTIC ALGORITHM*

Feature 1. Acute onset and fluctuating course. This information is usually obtained from a family member or nurse and is shown by positive responses to the following questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day—that is, tend to come and go or increase and decrease in severity?
Feature 2. Inattention. This feature is shown by a positive response to the following question: Did the patient have difficulty focusing attention—for example, was he or she easily distracted or did he or she have difficulty keeping track of what was being said?
Feature 3. Disorganized thinking. This feature is shown by a positive response to the following question: Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?
Feature 4. Altered level of consciousness. This feature is shown by any answer other than "alert" to the following question: Overall, how would you rate this patient's level of consciousness: alert (normal), vigilant (hyperalert), lethargic (drowsy, easily aroused), stupor (difficult to arouse), or coma (unable to arouse)?

*The diagnosis of delirium requires the presence of features 1 and 2 and either 3 or 4.
CAM = Confusion Assessment Method, from Inouye SK, van Dyck CH, Alessi CA, et al: Clarifying confusion: The Confusion Assessment Method. A new method for detection of delirium. *Ann Intern Med.* 1990;113:941-948. Training manual available at http://elderlife.med.yale.edu/pdf/The Confusion Assessment Method.pdf; DSM-IV = American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed., text revision. Washington, DC: American Psychiatric Association; 2000.

PATHOBIOLOGY

Similar to other common geriatric syndromes (Chapter 24), delirium usually has multiple causes. A search for the innumerable potential underlying contributors requires clinical astuteness and a thorough medical evaluation, especially because many of these factors are treatable but may result in substantial morbidity and mortality if left untreated. The process is made more challenging by the frequently nonspecific, atypical, or muted features of the underlying illness in older persons. Delirium is commonly the only initial sign of an underlying life-threatening illness such as pneumonia (Chapter 97), urosepsis (Chapter 292), or myocardial infarction (Chapter 73) in the older population.

The development of delirium usually involves a complex interrelationship between a vulnerable patient with pertinent predisposing factors and exposure to noxious insults or precipitating factors. Delirium may develop in vulnerable patients, such as cognitively impaired or severely ill patients, after a relatively benign insult, such as a single dose of sleeping medication. Conversely, in patients who are not vulnerable, delirium may develop only after exposure to multiple noxious insults. Previous studies have shown that the effects of these risk factors may be cumulative. Recognition of this multifactorial causation is important to the clinician because the removal or treatment of one factor in isolation usually is not sufficient to resolve the delirium. The full spectrum of vulnerability and precipitating factors should be addressed.

Predisposing factors, or factors that increase vulnerability, include preexisting cognitive impairment or dementia, severe underlying illness, high levels of comorbidity, functional impairment, advanced age, chronic renal insufficiency, dehydration, malnutrition, and vision or hearing impairment. Dementia is an important and consistent risk factor for delirium; demented patients have a twofold to fivefold increased risk for delirium. Of delirious patients, 30 to 50% have underlying dementia. Delirious patients commonly have evidence of underlying chronic brain disease, particularly conditions associated with cognitive impairment such as Alzheimer's disease, Parkinson's disease, or cerebrovascular disease.

Medications, the most common remediable cause of delirium, contribute to delirium in 40% of cases (Chapter 26). Insufficiency or failure of any major

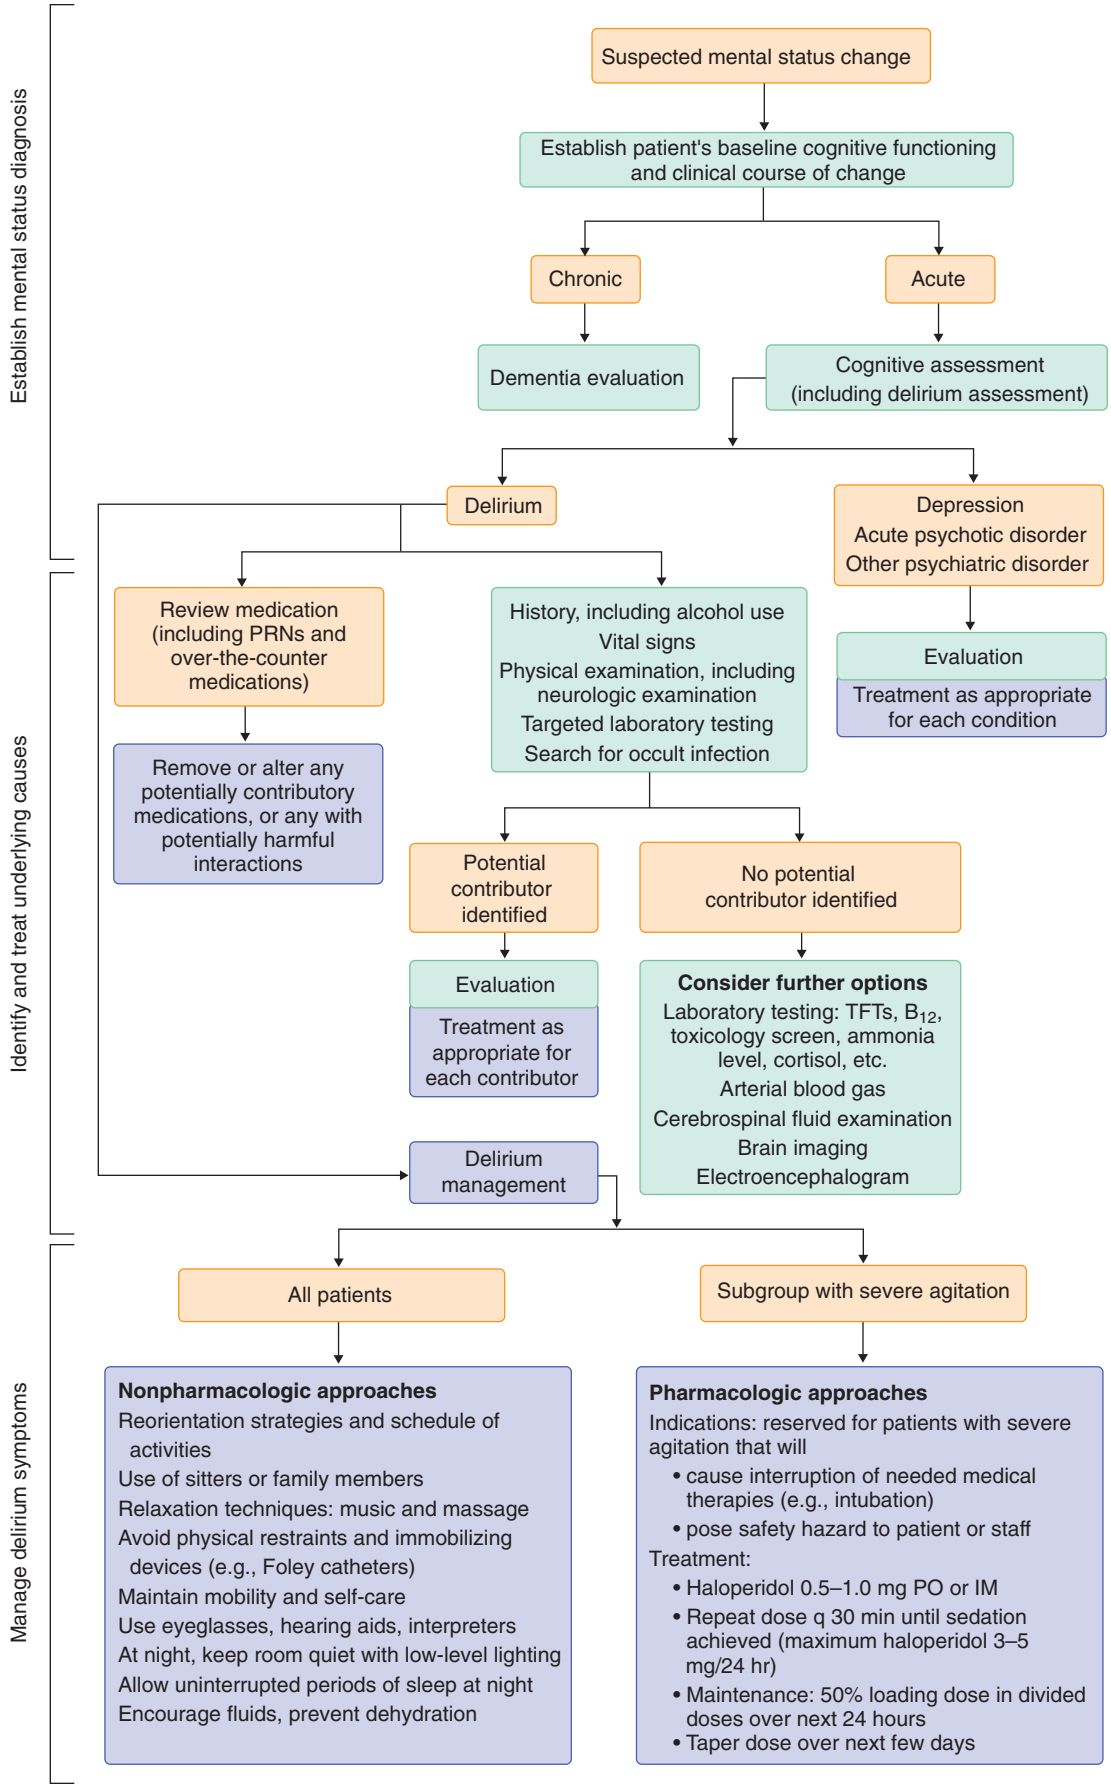

FIGURE 27-1. Algorithm for the evaluation of suspected mental status change in older patients. PRN = as needed; TFTs = thyroid function tests.

organ system, particularly renal or hepatic failure, can precipitate delirium. Hypoxemia and hypercarbia have been associated with delirium. Clinicians must be attuned to occult respiratory failure, which in the elderly often lacks the usual signs and symptoms of dyspnea and tachypnea and can be missed by the measurement of oxygen saturation alone. Acute myocardial infarction or heart failure can manifest as delirium in an elderly patient without the usual symptoms of chest pain or dyspnea. Occult infection is a particularly notable cause of delirium. Older patients frequently fail to mount the febrile or leukocytotic response to infection, and clinicians must assess them carefully for signs of pneumonia, urinary tract infection, endocarditis, abdominal abscess, or infected joints. A variety of metabolic disorders may contribute to delirium, including hypernatremia and hyponatremia, hypercalcemia, acid-base disorders, hypoglycemia and hyperglycemia, and thyroid or adrenal disorders. Immobilization and immobilizing devices (e.g., indwelling bladder catheters, physical restraints, bed alarms) are important factors in precipitating delirium. Dehydration and volume depletion and nutritional decline during hospitalization (e.g., weight loss, fall in serum albumin concentration) are well-documented factors contributing to delirium. Drug and alcohol withdrawal are important and often unsuspected causes of delirium in the elderly. Environmental factors, such as unfamiliar surroundings, sleep deprivation, deranged schedule, frequent room changes, sensory overload, and sensory deprivation, may aggravate delirium in the hospital. Psychosocial factors, such as depression, psychological stress, pain, and lack of social supports, also may precipitate delirium.

The basic pathogenesis of delirium is unclear. Most investigators agree that delirium seems to be a functional rather than a structural lesion. Electroencephalographic studies show global functional derangements in patients with delirium, characterized by generalized slowing of cortical background activity with the appearance of delta and theta activity. Neuroimaging studies coupled with cognitive testing demonstrate a generalized disruption in higher cortical function, with dysfunction in the prefrontal cortex, frontal and temporoparietal cortex, fusiform cortex, lingual gyri, subcortical structures, thalamus, and basal ganglia. The leading hypotheses for the pathogenesis of delirium focus on the roles of neurotransmission and inflammation. The most widely postulated mechanism for delirium is the failure of cholinergic transmission. Evidence supporting this hypothesis includes the frequent association of anticholinergic drugs with delirium, the reversal of delirium with procholinergic drugs such as physostigmine, the increased levels of serum anticholinergic activity in some delirious patients, and the benefit of cholinesterase inhibitors in some cases of delirium. Other neurotransmitter systems, such as dopamine, serotonin, tryptophan, norepinephrine, and γ-aminobutyric acid, may also play a role in delirium, but the evidence is less well developed. In some circumstances, such as infection or cancer, delirium may be mediated through cytokines, such as interleukin-2 and tumor necrosis factor. Although delirium has long been considered a transient syndrome, several of these basic mechanisms may not be completely reversible, particularly those resulting in hypoxic damage. Acute stress with high levels of cortisol may also contribute to delirium. The dose and duration of the noxious insult, along with the degree of vulnerability of the patient, also may exert great influence on the ultimate reversibility of the delirium.

CLINICAL MANIFESTATIONS

The cardinal features of delirium include acute onset and inattention. Establishing the acuteness of onset requires accurate knowledge of the patient's baseline cognitive function. Patients with delirium are inattentive; that is, they have difficulty focusing, maintaining, and shifting attention. They appear easily distracted and have difficulty maintaining conversation and following commands. Objectively, patients may have difficulty with simple repetitive tasks, digit spans, and recitation of months backward. Other key features include disorganized thought processes, which are usually a manifestation of underlying cognitive or perceptual disturbances; altered level of consciousness, which typically consists of lethargy with reduced awareness of the environment; and fluctuation of cognitive symptoms. Although not cardinal elements, other features that frequently occur during delirium include disorientation, cognitive deficits, psychomotor agitation or retardation, perceptual disturbances such as hallucinations and illusions, paranoid delusions, and sleep-wake cycle reversal.

DIAGNOSIS

The cornerstone of the evaluation of delirium is a comprehensive history and physical examination (Table 27-2). The first step is to establish the diagnosis of delirium through cognitive assessment and to determine whether the present condition represents an acute change from the patient's baseline cognitive function. Because cognitive impairment may not be apparent during conversation, brief cognitive screening tests, such as the Mini-Cog Test (Chapter 26) and the Confusion Assessment Method, should be used. Attention should be assessed further with other simple tests, such as a forward digit span (inattention is indicated by an inability to repeat five digits forward) or recitation of the months backward. A delirium assessment for nonverbal (e.g., intubated) patients, called the CAM-ICU, has been developed. The history, which should be obtained from a reliable informant, is targeted to establish the patient's baseline cognitive function and the time course of any mental status change and to obtain clues about potential precipitating factors, such as recent medication changes, intercurrent infection, or medical illness. Physical examination should include a detailed neurologic examination for focal deficits and a careful search for signs of occult infection or an acute abdominal process.

TABLE 27-2 EVALUATION OF DELIRIUM IN ELDERLY PATIENTS

Perform cognitive testing and determine baseline cognitive functioning: establish the diagnosis of delirium
Obtain a comprehensive history and perform a physical examination, including a careful neurologic examination for focal deficits and a search for occult infection
Review the patient's medication list: discontinue or minimize all psychoactive medications; check the side effects of all medications
Perform a laboratory evaluation (tailored to the individual): complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, calcium, phosphate, liver enzymes, oxygen saturation
Search for occult infection: physical examination, urinalysis, chest radiography, selected cultures (as indicated)
When no obvious cause is revealed after these steps, further targeted evaluation is considered in selected patients, as follows: Laboratory tests: magnesium, thyroid function, vitamin B_{12} level, drug levels, toxicology screen, ammonia level Arterial blood gas analysis: indicated in patients with dyspnea, tachypnea, any acute pulmonary process, or history of significant respiratory disease Electrocardiography: indicated in patients with chest or abdominal discomfort, shortness of breath, or cardiac history Cerebrospinal fluid examination: indicated when meningitis or encephalitis is suspected Brain imaging: indicated in patients with new focal neurologic signs or with a history or signs of head trauma Electroencephalography: useful in diagnosing occult seizure disorder and in differentiating delirium from nonorganic psychiatric disorders

Review of the patient's medication list, including over-the-counter medications, is crucial, and the use of medications with psychoactive effects should be discontinued or minimized whenever possible. In the elderly, these medications may cause psychoactive effects even at doses and measured drug levels within the "therapeutic range." Consideration should also be given to the possibility that withdrawal from alcohol or other medications is a contributor to delirium.

Laboratory Findings

Laboratory evaluation must be tailored to the individual situation (see Table 27-2). In patients with preexisting cardiac or respiratory diseases or related symptoms, electrocardiography or arterial blood gas determination may be indicated. The need for cerebrospinal fluid examination is controversial except when it is clearly indicated, such as in a febrile delirious patient. Brain imaging should be reserved for patients with new focal neurologic signs, those with a history or signs of head trauma, and those without another identifiable cause of the delirium. Electroencephalography, with a false-negative rate of 17% and a false-positive rate of 22% for distinguishing delirious from nondelirious patients, has a limited role and is most useful for detecting an occult seizure disorder and differentiating delirium from psychiatric disorders.

Differential Diagnosis

A crucial difficulty is distinguishing a long-standing confusional state (dementia) from delirium alone or delirium superimposed on dementia (see Fig. 27-1). These two conditions are differentiated by the acute onset of

TABLE 27-3 DELIRIUM RISK FACTORS AND POTENTIAL INTERVENTIONS

RISK FACTOR	INTERVENTION
Cognitive impairment	Reality orientation program (reorienting techniques, communication) Therapeutic activities program
Sleep deprivation	Noise reduction strategies Scheduling of nighttime medications, procedures, and nursing activities to allow uninterrupted period of sleep
Immobilization	Early mobilization (e.g., ambulation or bedside exercises) Minimal use of immobilizing equipment (e.g., bladder catheters)
Psychoactive medications	Restricted use of "as needed" sleep and psychoactive medications (e.g., sedative-hypnotics, narcotics, anticholinergic medications) Nonpharmacologic protocols for management of sleep and anxiety
Vision impairment	Provision of vision aids (e.g., magnifiers, special lighting) Provision of adaptive equipment (e.g., illuminated phone dials, large-print books)
Hearing impairment	Provision of amplifying devices Repair of hearing aids
Dehydration	Early recognition and volume repletion

symptoms in delirium (dementia is much more insidious) and the impaired attention and altered level of consciousness associated with delirium. The differential diagnosis also includes depression and nonorganic psychotic disorders. Although paranoia, hallucinations, and affective changes can occur with delirium, the key features of acute onset, inattention, altered level of consciousness, and global cognitive impairment assist in the recognition of delirium. At times, the differential diagnosis can be difficult, particularly with an uncooperative patient or when an accurate history is unavailable. Because of the potentially life-threatening nature of delirium, it is prudent to manage the patient as if he or she has delirium and to search for and treat underlying precipitants (e.g., intercurrent illness, metabolic derangement, drug toxicity) until further information can be obtained.

TREATMENT

Prevention

The most effective strategy to reduce delirium and its associated complications is primary prevention before delirium occurs. Preventive strategies should address important risk factors and target moderate- to high-risk patients at baseline (Table 27-3). Randomized trials have shown that a geriatrics consultation or a multidisciplinary intervention aimed at the risk factors for delirium can reduce the incidence of delirium by 40%. To date, no drug treatments, including cholinesterase inhibitors, have been effective in preventing delirium.■ On a larger scale, preventive efforts require systemwide changes to educate physicians and nurses and thus improve their recognition of delirium and heighten their awareness of its clinical implications, to provide incentives to change practice patterns that lead to delirium (e.g., immobilization, sleep medications, bladder catheters, physical restraints), and to create systems that enhance high-quality geriatric care (e.g., geriatric expertise, case management, clinical pathways, quality monitoring).

Medical Therapy

In general, nonpharmacologic approaches should be used in all delirious patients, and these are usually successful in managing symptoms. Pharmacologic approaches should be reserved for patients whose symptoms may result in the interruption of needed medical therapies (e.g., intubation, intravenous lines) or may endanger the safety of the patient or other persons. No drug is ideal for the treatment of delirium, however; any drug can cloud the patient's mental status further and obscure efforts to monitor the course of the mental status change. The drug should be given at the lowest dose and for the shortest time possible. Neuroleptics are the preferred agents. Haloperidol, the most widely used agent, causes less orthostatic hypotension and fewer anticholinergic side effects than thioridazine and is available in parenteral form; however, it has a higher rate of extrapyramidal side effects and acute dystonias. Second-generation antipsychotics have not proved superior to haloperidol.■ If parenteral administration is required, intravenous use results in a rapid onset of action, short duration of effect, and risk of hypotension and torsades de pointes; intramuscular use has a more optimal duration of action and is preferred. The recommended starting dose is 0.25 to 0.5 mg of haloperidol orally or intramuscularly, repeated every 30 minutes after the vital signs have been rechecked, until sedation has been achieved. The end point should be an awake but manageable patient. The average elderly patient who has not been treated previously with neuroleptics should require a total loading dose of no more than 3 to 5 mg of haloperidol. Subsequently, a maintenance dose consisting of half the loading dose should be administered in divided doses during the next 24 hours, with doses tapered over the next few days as the agitation resolves.

Benzodiazepines are not recommended as the first-line treatment of delirium because of their tendency to cause oversedation and exacerbate the confusional state. They remain the drugs of choice, however, for the treatment of withdrawal syndromes from alcohol and sedative drugs (Chapters 32 and 33).

Nonpharmacologic Management

Multicomponent geriatric interventions may be effective in improving quality of life without increasing health care costs.■ Nonpharmacologic management techniques recommended for every delirious patient include encouraging the presence of family members, using "sitters" as orienting influences, and transferring a disruptive patient to a private room or closer to the nurse's station for increased supervision. Interpersonal contact and communication, including verbal reorientation strategies, simple instructions and explanations, and frequent eye contact, are vital. Patients should be involved in their own care and allowed to participate in decision making as much as possible. Eyeglasses and hearing aids may reduce sensory deficits. Mobility, self-care, and independence should be encouraged, and physical restraints and bed alarms should be avoided, if possible, because of their tendency to increase agitation, their lack of efficacy, and their potential to cause injury. Attention must be focused on minimizing the disruptive influences of the hospital environment. Clocks and calendars should be provided to assist with orientation. Room and staff changes should be kept to a minimum. A quiet environment with low-level lighting is optimal for delirious patients. Perhaps the most important intervention is to schedule the checking of vital signs, the administration of medications, and the performance of procedures to allow the patient's uninterrupted sleep at night. Nonpharmacologic approaches to relaxation, including music, relaxation tapes, and massage, can be highly effective in managing agitation.

End-of-Life Care

Delirium occurs in at least 80% of patients at the end of life and is considered part of the dying process by many hospice care providers (Chapter 3). Establishing the goals for care in advance with the patient and family is critical to guide appropriate management. For example, some patients may prioritize the preservation of alertness and the ability to communicate with loved ones as long as possible; others may prioritize comfort above all else. Physicians must be aware that even in terminal patients, many causes of delirium are potentially reversible with simple interventions such as adjusting medications, providing oxygen, or treating dehydration; however, aggressive diagnostic evaluation is usually inappropriate in this population. Nonpharmacologic measures to treat agitation and delirium should be instituted in all patients (including massage, music, and relaxation therapies). Haloperidol remains the first-line therapy for delirium in terminally ill patients. If more sedation is indicated, a short-acting benzodiazepine such as lorazepam (starting dose, 0.5 to 1.0 mg PO, IM, or SL), which is easily titrated, is recommended in this setting. Because sedation may result in decreased interaction and communication, increased confusion, and respiratory depression, this choice should be made in conjunction with the family.

PROGNOSIS

Delirium is an important independent determinant of prolonged hospital stay, increased mortality, higher health care costs, increased rates of institutional placement, and functional and cognitive decline—even after controlling for age, gender, dementia, illness severity, and baseline functional status. Delirium was previously considered a reversible, transient condition, but more recent studies on the duration and persistence of symptoms document that delirium may be much more persistent than previously believed. Delirium typically lasts for 30 days or more, and only 20% of patients have complete resolution of all symptoms at 6-month follow-up. Delirium seems to have greater deleterious effects in patients with underlying cognitive impairment. The long-term detrimental effects are most likely related to the duration, severity, and underlying cause of the delirium and the vulnerability of the patient.

FUTURE DIRECTIONS

Because delirium is common, frequently iatrogenic, and linked to processes of care, it is considered to be a marker of the quality of care and patient safety in the hospital setting. Strategies to prevent delirium are a priority. It is hoped that future research will elucidate the pathophysiologic mechanisms of delirium by the use of neuroimaging modalities, neuropsychological testing, and genetic and laboratory markers; clarify the contribution of delirium to irreversible cognitive impairment; and improve the evidence-based management of delirium.

PRINCIPLES OF DRUG THERAPY

ROBERT B. DIASIO

Under different conditions, a drug may produce diverse effects ranging from no effect to a desirable effect to an undesirable toxic effect. Physicians must learn how to individualize the drug dosage under different conditions to ensure effective and safe therapy. This necessitates understanding the pharmacokinetics—the movement of a drug over time through the body—and the pharmacodynamics—the relationship between drug concentration and drug effect (Fig. 28-1). This chapter reviews the basic concepts of pharmacokinetics and pharmacodynamics, followed by guidelines on how to use this information to optimize therapeutic applications. Drug interactions and adverse drug responses are briefly discussed, with advice on how both can be recognized and minimized in clinical practice.

PHARMACOKINETIC PRINCIPLES

Administration

The most efficient and straightforward means of administering a drug into the systemic circulation is by intravenous injection of the drug as a bolus. With this route, the full amount of a drug is delivered to the systemic circulation almost immediately. The same dose also may be administered as an intravenous infusion over a longer period, resulting in a decrease in the peak plasma concentration and an accompanying increase in the time the drug is present in the circulation. Many other routes of administration can be used, including sublingual, oral, transdermal, rectal, inhalational, subcutaneous, and intramuscular; each of these routes carries not only a potential delay in the time it takes the drug to enter the circulation but also the possibility that a large fraction of it will never reach the circulation.

Absorption

Absorption refers to the transfer of a drug from the site of administration to the systemic circulation. Many drugs cross a membrane barrier by passive diffusion and enter the systemic circulation. Because passive diffusion in this setting depends on the concentration of the solute at the membrane surface, the rate of drug absorption is affected by the concentration of free drug at the absorbing surface. Factors that influence the availability of free drug thus affect drug absorption from the administration site; this effect can be exploited to design medications that release a drug slowly into the circulation by prolonging drug absorption. With certain sustained-released oral preparations, the rate of dissolution of the drug in the gastrointestinal tract determines the rate at which the drug is absorbed (e.g., timed-release antihistamines). Similarly, a prolonged drug effect can be obtained by the use of transdermal medications (e.g., nitroglycerin) or intramuscular depot preparations (e.g., benzathine penicillin G).

First-Pass Effect

Some drugs that are administered orally are absorbed relatively well into the portal circulation but are metabolized by the liver before they reach the systemic circulation. Because of this "first-pass" or "presystemic" effect, the oral route may be less suitable than other routes of administration for such drugs. A good example is nitroglycerin, which is well absorbed but efficiently metabolized during the first pass through the liver. The same drug can achieve adequate systemic levels when it is given sublingually or transdermally.

Bioavailability

The extent of absorption of a drug into the systemic circulation may be incomplete. The bioavailability of a particular drug is the fraction (F) of the total drug dose that ultimately reaches the systemic circulation from the site of administration. This fraction is calculated by dividing the amount of the drug dose that reaches the circulation from the administration site by the amount of the drug dose that would enter the systemic circulation after direct intravenous injection into the circulation (essentially the total dose). Bioavailability, or F, can range from 0, in which no drug reaches the systemic circulation, to 1.0, in which essentially all the drug is absorbed. The bioavailability of a drug may vary in different formulations because the overall absorption differs. This variability has become a concern with the increasing use of generic preparations.

Distribution

After delivery of a drug into the systemic circulation either directly by intravenous injection or after absorption, the drug is transported throughout the body, initially to the well-perfused tissues and later to areas that are less perfused. The distribution phase can be assessed best by plotting the drug's plasma concentration on a log scale versus time on a linear scale (Fig. 28-2). For an intravenously administered drug, when absorption is not a factor, the initial phase—from immediately after administration through the rapid fall in concentration—represents the distribution phase, during which a drug rapidly disappears from the circulation and enters the tissues. This is followed by the elimination phase (see later), when drug in the plasma is in equilibrium with drug in the tissues. During this latter phase, the drug's plasma concentration is thought to be related to drug effect.

Volume of Distribution

The volume of distribution (VD) relates the amount of drug in the body to the concentration of drug in the plasma. It is calculated by dividing the dose that ultimately gets into the systemic circulation by the plasma concentration at time zero (C_{p0}):

$$VD = dose/C_{p0} \quad (1)$$

The C_{p0} can be calculated by extrapolating the elimination phase back to time zero (see Fig. 28-2). The VD is best considered the "apparent VD" because it represents the apparent volume needed to contain the entire amount of the drug, assuming it is distributed throughout the body at the same concentration as in the plasma. Table 28-1 lists pharmacokinetic data for commonly used drugs from several drug classes, showing the wide variation in VD. Digoxin, for example, has a large VD (>5 L), whereas glimepiride has a relatively small VD (0.18 L). As discussed later, VD is a useful pharmacokinetic tool for calculating the loading dose and appreciating how various changes can affect a drug's half-life.

Elimination

Drugs are removed from the body by two major mechanisms: hepatic elimination, in which drugs are metabolized in the liver and excreted through the biliary tract; and renal elimination, in which drugs are removed from the circulation by either glomerular filtration or tubular secretion. For most drugs, the rates of hepatic and renal elimination are proportional to the plasma concentration of the drug. This relationship is often described as a "first-order" process. Two measurements, clearance and half-life, are used to evaluate elimination.

Clearance

The efficiency of elimination can be assessed by quantifying how fast the drug is cleared from the circulation. Drug clearance is a measure of the volume of plasma cleared of drug per unit of time. It is similar to the clinical measurement used to assess renal function—creatinine clearance, which is the volume of plasma from which creatinine is removed per minute. Total drug clearance (Cl_{tot}) is the rate of elimination by all processes (El_{tot}) divided by the plasma concentration of the drug (C_p):

$$Cl_{tot} = El_{tot}/C_p \quad (2)$$

Drugs may be cleared by several organs, but as noted earlier,. renal clearance and hepatic clearance are the two major mechanisms. Total drug clearance (Cl_{tot}) can best be described as the sum of clearances by each organ. For most drugs, this is essentially the sum of renal clearance and hepatic clearance:

$$Cl_{tot} = Cl_{Ren} + Cl_{Hep} \quad (3)$$

Table 28-1 shows the wide variation in clearance values among commonly used medications; some drugs (e.g., phenobarbital) have relatively low clearances (<5 mL/minute), and other drugs (e.g., aspirin) have relatively high clearances (>500 mL/minute). Tobramycin is cleared almost entirely by the kidneys, whereas aspirin, carbamazepine, and phenytoin are cleared less than 5% by the kidneys.

Drug clearance is affected by several factors, including blood flow through the organ of clearance, protein binding to the drug, and activity of the clearance processes in the organs of elimination (e.g., glomerular filtration rate and tubular secretion in the kidney, enzyme activity in the liver). Drug clearance

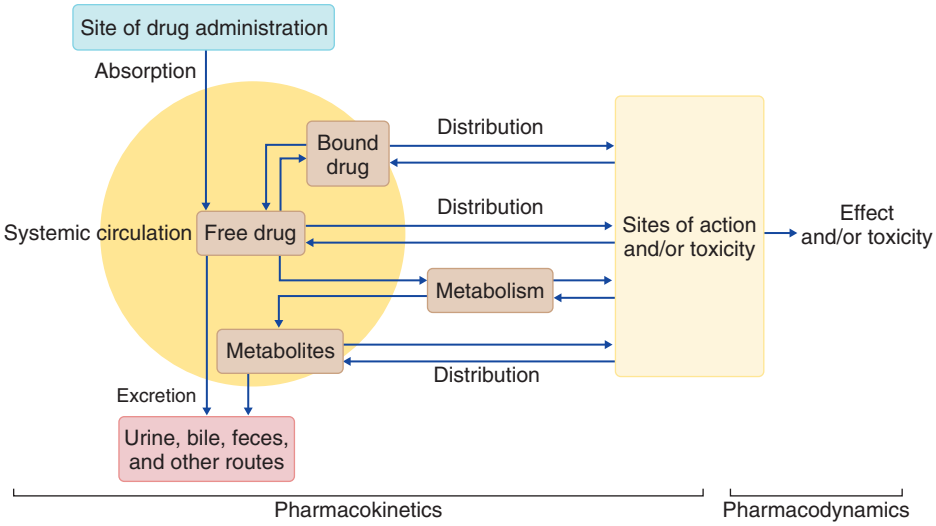

FIGURE 28-1. Schematic of a drug's movement through the body, from the site of administration to production of a drug effect. The relationship between pharmacokinetics and pharmacodynamics is shown.

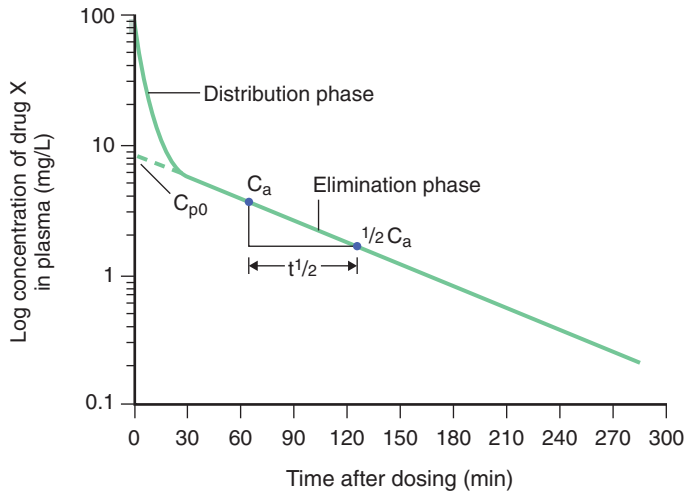

FIGURE 28-2. Representative drug concentration versus time plot used in pharmacokinetic studies. Concentration of drug is plotted with a logarithmic scale on the ordinate, and time is plotted with a linear scale on the abscissa. The resultant curve has two phases: the distribution phase, which is the initial portion of the plotted line when the concentration of drug decreases rapidly; and the later elimination phase, during which there is an exponential disappearance of drug from the plasma over time. The dotted line extrapolated from the elimination phase back to time zero is used to calculate plasma concentration at time zero (C_{p0}). During the elimination phase, the half-life ($t_{1/2}$) can be calculated as the time it takes to decrease the concentration by half (shown here as the time needed to decrease from concentration C_a to $\frac{1}{2}$ C_a).

is not affected by the distribution of drug throughout the body (VD) because clearance mechanisms act only on drug in the circulation.

Half-life

The amount of time needed to eliminate a drug from the body depends on the clearance and the VD. The first-order elimination constant (K_e) represents the proportion of the apparent VD that is cleared of drug per unit of time during the drug's exponential disappearance from the plasma over time (elimination phase):

$$K_e = \text{Cl}/\text{VD} \quad (4)$$

The value of this constant for a particular drug can be determined by plotting drug concentration versus time on a log-linear plot (see Fig. 28-2) and measuring the slope of the straight line obtained during the exponential (elimination) phase.

The time needed to eliminate the drug is best described by its half-life ($t_{1/2}$), which is the time required during the elimination phase (see Fig. 28-2) for the plasma concentration of the drug to be decreased by half. Mathematically, the half-life is equal to the natural logarithm of 2 (representing a reduction of drug concentration to half) divided by K_e. Substituting for K_e from Equation 4 and calculating the natural logarithm of 2, the half-life can be represented by the following equation:

$$t_{1/2} = 0.693\ \text{VD}/\text{Cl} \quad (5)$$

From this equation, one can predict that at a given clearance, as the VD increases, the half-life increases. Similarly, at a given VD, as the clearance increases, the half-life decreases. Clinically, many disease states (see later) can affect VD and clearance. Because disease affects VD and clearance differently, the half-life may increase, decrease, or not change much at all. Therefore, the half-life by itself is not a good indicator of the extent of abnormality in elimination.

The half-life is useful to predict how long it takes for a drug to be eliminated from the body. For any drug that has a first-order elimination, one would expect that by the end of the first half-life, the drug would be reduced to 50%; by the end of the second half-life, to 25%; by the end of the third half-life, to 12.5%; by the end of the fourth half-life, to 6.25%; and by the end of the fifth half-life, to 3.125%. In general, a drug can be considered essentially eliminated after three to five half-lives, when less than 10% of the effective concentration remains. Table 28-1 shows the wide variation in half-life for several commonly used drugs.

APPLYING PHARMACOKINETIC PRINCIPLES

Using a Loading Dose

To attain a desired therapeutic concentration rapidly, a loading dose is often used. In determining the amount of drug to be given, the physician must consider the "volume" within the body into which the drug will be distributed. This volume is best described by the apparent VD. The loading dose can be calculated by multiplying the desired concentration by the VD:

$$\text{Loading dose} = \text{desired concentration} \times \text{VD} \quad (6)$$

Rapid administration of the entire loading dose may produce an initially high peak concentration that results in toxicity. This problem can be avoided either by administering the loading dose as a divided dose or by varying the rate of access to the circulation, such as by administering the drug as an infusion (with an intravenous drug) or by taking advantage of the slower access to the circulation from various other routes (e.g., oral dosing). This approach is illustrated by phenytoin (see Table 28-1), which may need to be administered with a loading dose to achieve a therapeutic level (10 to 20 mg/L) rapidly. Because the VD for phenytoin is approximately 0.6 L/kg, the loading dose calculated from Equation 6 is 420 mg/L to attain a minimally therapeutic level of 10 mg/L in a 70-kg adult. However, administration of 420 mg of phenytoin by intravenous bolus carries the risk of cardiac arrest and death. By taking advantage of the reduced bioavailability (F = 0.8) and slow absorption of oral phenytoin, the loading dose can be administered safely as an oral dose of 500 mg.

The equation for the loading dose can also be used to calculate the dose needed to "boost" an inadequate blood level of drug to a desired therapeutic range. If therapeutic monitoring shows that the phenytoin level is 5 mg/L and the desired level is 15 mg/L, it is necessary to multiply the difference needed to achieve the desired concentration (10 mg/L) by the VD

TABLE 28-1 PHARMACOKINETIC PARAMETERS FOR SOME COMMONLY USED DRUGS

DRUG	VD (L/KG)	PROTEIN BINDING (%)	TOTAL CLEARANCE (ML/MIN)	% OF TOTAL CLEARANCE AS RENAL CLEARANCE	HALF-LIFE (HR)	THERAPEUTIC RANGE (MG/L)
Amoxicillin	0.47	17-18		86	1.2	2-8
Aspirin (acetylsalicylic acid)	0.14-0.18	80-90	575-725	<2	0.2-0.3	20-250
Carbamazepine	1.2	75-90	50-125	1-3	12-17	4-12
Digoxin	5-7.3	20-30	75	50-70	34-44	0.5-2
Glimepiride	0.18	>99.5	0.62 ± 0.26	<0.5	3.4 ± 2.0	
Lidocaine	3	60-80	700	<10	1.5-2	1-5
Lithium carbonate	0.7-1	0	20-40	95-99	20-270	0.4-1.4*
Penicillin G	0.5-0.7	45-68	—	20	0.4-0.9	Variable
Phenobarbital	0.6-0.7	20-45	4	25	2-6 days	<10-40*
Phenytoin	0.4-0.8	88-93	—	<5	7-26	10-20
Procainamide	2.2	14-23	470-600	40-70	2.5-4.7	4-8
Theophylline	0.3-0.7	60	36-50	<10	4-16	5-20
Tobramycin	0.25-0.30	<10	70	>95	2-4	0.5-2 (TR) 4-8 (PK)
Vancomycin	0.4-1	52-60	65	85	4-6	5-10 (TR) 25-35 (PK)

*Therapeutic range varies according to the indication for the drug. For example, lithium carbonate in the range of 0.4-1.3 mg/L is appropriate for affective schizophrenia disorder; a range of 1.0-1.4 mg/L is appropriate for mania. Phenobarbital concentration below 10 mg/mL is appropriate for anticonvulsant therapy; 40 mg/L is appropriate as a hypnotic.
PK = peak value; TR = trough value; VD = volume of distribution.

(0.6 L/kg) to determine the dose (in milligrams per kilogram) necessary to achieve this drug level after distribution. In a 70-kg individual, 0.6 mg/kg is multiplied by 70 kg to obtain the calculated loading dose (420 mg) that can be administered safely. A 500-mg oral dose with a bioavailability of less than 1 (e.g., F = 0.8) would deliver to the systemic circulation the approximate amount needed and avoid the risks associated with rapid intravenous administration.

Determining Drug Accumulation

Continuing to administer a drug, either as a prolonged infusion or as repeated doses, results in accumulation until a steady state occurs. Steady state is the point at which the amount of drug being administered equals the amount being eliminated so that the plasma and tissue levels remain constant. The elimination half-life determines not only the time course of drug elimination but also the time course of drug accumulation. This "mirror image" pattern of drug accumulation and elimination is illustrated in Figure 28-3. As with drug elimination, three to five half-lives determine the time it takes to reach steady state during drug accumulation. Whereas drugs with short half-lives accumulate rapidly, drugs with long half-lives require a longer time to accumulate, with a potential delay in achieving therapeutic levels. For drugs with long half-lives, a loading dose may be needed to obtain rapid drug accumulation and a more rapid therapeutic effect.

With each change in drug dose or rate of infusion, a change in steady state occurs. Although it is not obvious for drugs with short half-lives, the effects of dose adjustments for drugs with longer half-lives are delayed, and the time varies directly with the drug's half-life.

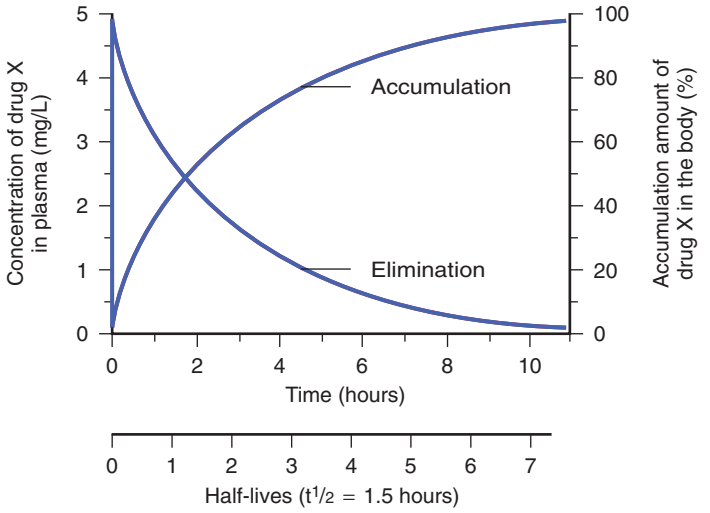

FIGURE 28-3. Representative plot of the "mirror image" relationship between the elimination of drug (after drug is discontinued) and the accumulation of drug (during infusion). The plot shows the concentration on the left *y*-axis and time on the upper *x*-axis. The lower *x*-axis shows the time in half-lives, and the *y*-axis on the right shows the percentage of drug in the body. After three to five half-lives, elimination is essentially complete, and accumulation is essentially at a steady state.

Using a Maintenance Dose

After steady state is reached in three to five half-lives with either a continuous infusion or intermittent doses, the rate of drug administered equals the rate of drug eliminated. For an intravenous drug, the administration rate is the infusion rate (I); for a drug administered by another route (e.g., orally), the administration rate is the dose per unit of time (D/t). Equation 7 shows that the rate of elimination (total) equals $Cl_{tot} \times C_p$. With an intravenously administered drug, because the infusion rate equals the elimination rate at steady state, it follows that

$$I = Cl_{tot} \times C_p \quad (7)$$

Similarly, with an orally administered drug, the dose administered per unit of time equals the elimination rate at steady state, with the result that

$$D/t = Cl_{tot} \times C_p \quad (8)$$

These equations show the direct relationship between the dose and the resultant plasma concentration at steady state. This relationship is independent of the distribution of the drug. By use of these equations, it is possible to determine the infusion rate or the interval and dose needed to achieve and maintain a specified drug concentration in the plasma.

When a drug is administered intermittently, it approaches steady-state concentration over time, with a pattern similar to that observed with continuous infusion (Fig. 28-4). With intermittent drug administration, such as with an oral dose, the drug concentration fluctuates; the magnitude of fluctuation between the peak and trough concentrations depends on the interval of administration, drug half-life, absorption characteristics, and site of administration. The effect of a change in the interval of administration for an oral drug is shown in Figure 28-4. As the intervals decrease below the half-life, the fluctuation decreases and approaches the curve produced by an intravenous infusion. Orally administered drugs may reach the blood stream more

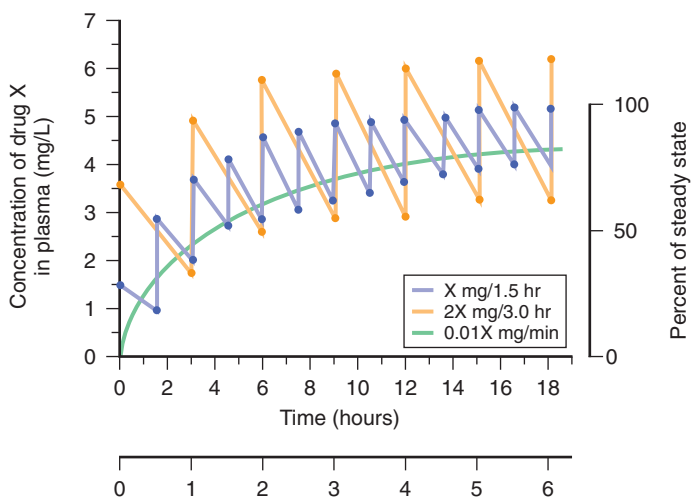

FIGURE 28-4. Accumulation of drug over time, approaching a steady state. Time is depicted in hours (upper *x*-axis) and half-lives (lower *x*-axis, showing that steady state is reached in three to five half-lives). The green line depicts the pattern produced by an infusion of a hypothetical drug at a dose of 0.01X. The orange line shows the pattern resulting from oral administration of a 2X dose every 3 hours, and the blue line represents the pattern produced by oral administration of dose X every 1.5 hours.

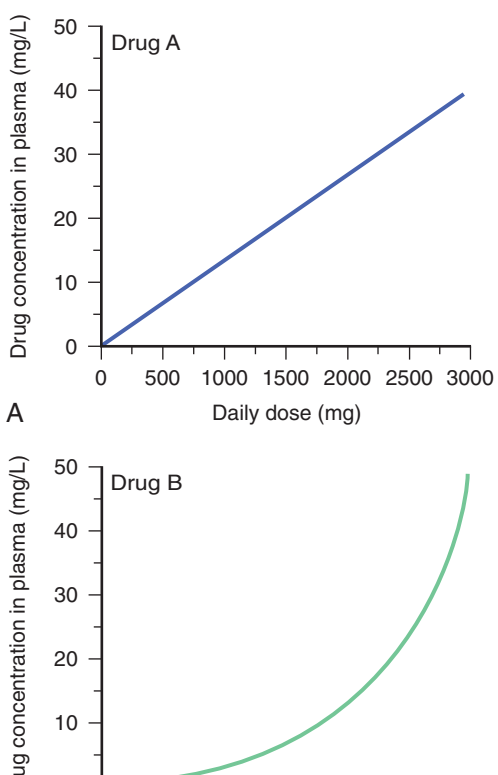

FIGURE 28-5. Effect of increasing the dose of a drug on its serum concentration. A, Drug A follows first-order or linear kinetics. **B,** Drug B follows zero-order or nonlinear (or saturable) kinetics.

rapidly, attaining a higher peak concentration with one formulation, whereas the same drug administered as a timed-release formulation is absorbed more slowly, with a lower peak concentration but lasting longer in the plasma. Finally, the same drug administered by different routes may have different plasma profiles not only because of differing absorption characteristics but also because of other effects, such as first-pass metabolism.

Decreasing the Drug Level

At times, it may be necessary to decrease the plasma drug level while maintaining therapy (e.g., when signs of toxicity become apparent or a potentially dangerously high concentration of drug is noted; see later). The most effective and rapid response is to discontinue the drug; the length of time for which the drug is discontinued is determined by the estimated half-life of the drug in the specific patient. After discontinuation of the drug for a time based on its half-life, the total clearance (Cl_{tot}) of the drug can be used to determine what infusion rate (I, Equation 7) or dose and interval (D/t, Equation 8) must be used to achieve the new desired concentration (C_p).

Effect of Dose Increases on Elimination Kinetics

Although the previously discussed pharmacokinetic principles can be a guide to the dose of most drugs, not all drugs behave the same when the dose is increased. The elimination of most drugs follows first-order or linear kinetics; the amount of drug eliminated is directly proportional to the concentration of drug in the plasma (Fig. 28-5A). A few drugs have a different pattern of elimination. Three of the most commonly used drugs that exhibit this different pharmacokinetic pattern are ethanol, phenytoin, and salicylate. These drugs have dose-dependent, nonlinear saturation kinetics. As the dose of drug increases and the concentration of drug in the plasma rises, the relative amount of drug being eliminated falls (i.e., the clearance decreases) until the rate of drug metabolism is at its maximum. At this point, drug elimination is said to be zero order, and the drug concentration in plasma starts to increase much more (no longer linearly) with each subsequent increase in dose (Fig. 28-5B).

MONITORING DRUG CONCENTRATION AS A GUIDE TO THERAPY

Although published pharmacokinetic data (usually population averages) such as those in Table 28-1 are useful to determine initial drug dosing, modification of the dose may be needed in an individual patient. For some drugs (e.g., certain antihypertensives or anticoagulants), the therapeutic effects (e.g., blood pressure or coagulation) can be quantified easily over a range of concentrations, permitting adequate drug adjustment. For many other drugs (e.g., some antiarrhythmics or antiseizure medications), therapeutic effects over a range of concentrations are not readily detectable. With these drugs, the plasma concentration may provide further guidance in optimizing therapy if the plasma concentration of the drug is a reflection of its concentration at the site of action and the drug effects are reversible. A third, much smaller group of drugs produces irreversible effects (e.g., aspirin inhibition of platelet aggregation). With these drugs, plasma drug concentration does not correlate with drug effect, and drug monitoring is not useful.

To use drug concentration as a guide to therapy, it is necessary to establish a range of concentrations from minimally to maximally efficacious with tolerable toxicity. This range of concentrations, or the *therapeutic window,* is usually determined from a dose-response curve generated from a population of patients who have been examined closely for therapeutic and toxic effects (Fig. 28-6). This graph also may be used to determine the *therapeutic index,* a useful measure of drug toxicity calculated by dividing the 50% value from the toxicity curve by the 50% value from the efficacy curve. Because these curves are generated from population data, the values may not be applicable to all individuals.

Table 28-1, in addition to providing useful pharmacokinetic data, lists therapeutic ranges of several common drugs for which measuring the concentration and knowing the therapeutic range may be useful in clinical management. Many of these drugs are used to treat serious or life-threatening diseases. In these cases, it is essential to avoid inadequate doses because a therapeutic effect is needed. Excessive doses must also be avoided because of the risk of toxicity with drugs that have a small therapeutic index. In contrast, it is not necessary to assay levels of drugs used to treat noncritical diseases (when inadequate treatment is not a serious problem) or for which the therapeutic index is large (when relative overtreatment is not likely to produce toxicity).

Problems with Interpreting Drug Concentration

The time of blood collection, perhaps more than any other factor, contributes to the misinterpretation of drug levels. As can be seen in Figure 28-2, if sampling is performed too early, while the drug is still in the distribution phase, the drug level may be high and not reflect drug concentration at the site of action. It is therefore important to sample after the distribution phase.

For many drugs administered intermittently, a trough level, obtained immediately before the next dose is administered, is most useful for making decisions about dose adjustments (see Table 28-1). For drugs administered by infusion or intermittently at short intervals (see Fig. 28-4), the best time to draw blood is during steady state.

Protein binding is another major factor that contributes to the misinterpretation of drug levels. Free drug (not bound to protein and able to equilibrate with tissues and to interact with the site of action) is the critical drug concentration when therapeutic decisions are being made. Many drugs are tightly bound to plasma protein, however. Table 28-1 shows that many commonly used drugs, such as aspirin, carbamazepine, phenytoin, and glimepiride, have protein binding of more than 75%. Because many of the commonly used drug assays determine total drug concentration (which includes protein-bound drug and free drug), assessment of the "true" free drug concentration may be inaccurate, particularly if the fraction of drug bound to protein varies. In addition, the drug's binding may be decreased by disease or by other drugs, leading to increased unbound drug levels that alter the interpretation of the measured drug concentrations. Kidney and liver disease can change the binding of certain drugs (e.g., phenytoin) to protein because of a decrease in protein (e.g., decreased albumin, as in nephrotic syndrome or liver disease) or as a result of competition for protein binding by endogenously produced substances (e.g., uremia in kidney disease, hyperbilirubinemia in liver disease). Similarly, other drugs may compete for binding to protein. A major problem secondary to these changes in protein binding is that free drug is not typically measured in many of the common drug assays used by clinical laboratories. Last, changes in drug binding to protein can affect the pharmacokinetics of the drug, the main effect being on the VD, which increases as protein binding decreases.

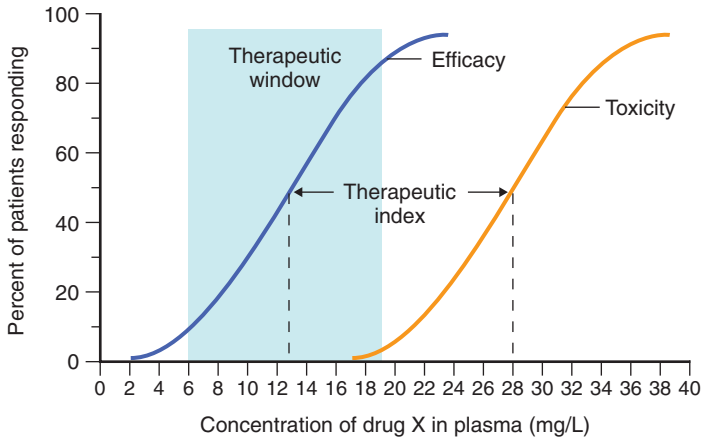

FIGURE 28-6. Pattern produced in a dose-response population study in which both effect and toxicity are measured. The therapeutic window is shown as the range of therapeutically effective concentrations, which includes most of the efficacy curve and less than 10% of the toxicity curve. The therapeutic index is calculated by dividing the 50% value on the toxicity curve by the 50% value on the efficacy curve.

The usefulness of a drug assay is also limited by physiologic changes that may alter the response at a particular drug concentration. An example of this pharmacodynamic change is the response produced by a certain level of digoxin in the presence of altered electrolyte concentrations (e.g., potassium, calcium, magnesium). Tolerance, a reduced response to a given concentration of drug with continued use, is another pharmacodynamic change that may alter how a drug concentration is interpreted. Tolerance is commonly observed with the continued use of narcotics (e.g., in terminal cancer patients); initially, adequate pain control is noted at a given drug concentration, but after long-term administration, the same drug concentration is no longer associated with pain relief.

ADJUSTING DRUG DOSE WITH DISEASE

Kidney Disease

The major questions to be answered when determining whether a drug dosage needs to be adjusted in the setting of kidney disease are the following: Is the drug primarily excreted through the kidneys? Are increased drug levels likely to be associated with toxicity? If the answer to both is yes, it is likely that with decreased renal clearance, a drug will accumulate and become toxic. With renal failure, it is necessary to adjust the dosing regimen of such drugs, particularly for a drug with a long half-life and a small therapeutic index (e.g., digoxin).

To obtain the desired concentration over time in the presence of decreased clearance, adjustments can be made by decreasing the dose while maintaining the dose interval (DD), maintaining the dose but increasing the interval between doses (II), or a combination of both (DD and II). Table 28-2 shows how these three different methods are used to adjust the dosages of several common drugs to account for renal dysfunction (see Table 28-1 for their pharmacokinetic properties with normal renal function). With these

TABLE 28-2 ADJUSTMENT OF DRUG DOSAGE IN RENAL FAILURE

DRUG	TYPE OF ELIMINATION	*Half-Life (hr)* NORMAL	*Half-Life (hr)* END-STAGE RENAL DISEASE	METHOD*	*Adjustment for Renal Failure* GFR >50 ML/MIN	*Adjustment for Renal Failure* GFR 10-50 ML/MIN	*Adjustment for Renal Failure* GFR <10 ML/MIN	*Adjustment for Renal Failure* REMOVED BY DIALYSIS†

*DD (alone) = decrease dose (maintain same interval); II (alone) = increase interval between doses (maintain dose); DD and II (together) = combination of both approaches.
†Dialysis refers to hemodialysis.
GFR = glomerular filtration rate.

adjustments, it may be possible to achieve an average concentration similar to that obtained with normal renal function; however, there may be concomitant marked changes in the magnitude of peak and trough values. In choosing the type of drug adjustment, the physician should consider not only the therapeutic index of the drug but also (1) whether an effective concentration must be achieved quickly and maintained within a narrow range (i.e., maintaining an average drug concentration and avoiding trough levels at which the drug is ineffective) and (2) whether toxicity is associated with elevated (i.e., peak) drug concentrations.

Renal drug clearance correlates with creatinine clearance (whether the drug uses glomerular filtration or tubular secretion); therefore, any adjustment of drug dose in kidney disease can use the creatinine clearance to calculate the dose needed because renal drug clearance is proportional to creatinine clearance. The creatinine clearance (Cl_{Cr}), which is used as an estimate of glomerular filtration rate, may be calculated directly from the serum creatinine concentration by the following equation:

$$Cl_{cr} = [(140 - \text{age}) \times \text{weight (kg)}]/[72 \times \text{serum creatinine (mg/dL)}] \quad (9)$$

The calculated creatinine clearance should be multiplied by 0.85 for females. (*Note:* This calculation applies only when the serum creatinine concentration is less than 5 mg/dL and renal function is not rapidly changing.)

Using Clearance for Dose Adjustment

The dose of a drug used in renal insufficiency ($dose_{D\text{-}RI}$) is proportional to the dose used with normal renal function ($dose_D$) in the same ratio as clearance of the drug in renal insufficiency ($Cl_{D\text{-}RI}$) to clearance with normal renal function (Cl_D). By rearranging, $dose_{D\text{-}RI}$ is defined as:

$$Dose_{D\text{-}RI} = dose_D \times [Cl_{D\text{-}RI}/Cl_D] \quad (10)$$

One can estimate the $Cl_{D\text{-}RI}$ by multiplying Cl_D by the ratio of the creatinine clearance in renal insufficiency ($Cl_{Cr\text{-}RI}$) over Cl_{Cr} with normal renal function:

$$Cl_{D\text{-}RI} = Cl_D \times [Cl_{Cr\text{-}RI}/Cl_{Cr}] \quad (11)$$

As shown in Equation 3, total clearance is the sum of clearance by renal and nonrenal (typically hepatic) mechanisms. Any nonrenal clearance is assumed to remain normal, and only the renal clearance is adjusted, with total clearance being reduced only to the extent that renal clearance is reduced. The dose may be calculated from the total (adjusted) clearance and the desired plasma concentration by either Equation 7 or Equation 8. The calculated dose is only an initial guide to the dose needed, however. By monitoring the drug response or the plasma drug concentration at various times after initial dosing, further dose adjustments can be made as necessary. From a practical perspective, most clinical dose adjustments in the presence of renal dysfunction can be guided by published tables based on changes in glomerular filtration rate (see Table 28-2) and the effectiveness of dialysis in removing the drug. Computerized decision support systems are particularly effective in guiding medication dosing for inpatients with renal insufficiency.

Loading Dose in Renal Insufficiency

For drugs typically administered with a loading dose in patients with normal renal function, the same approach can be used in those with renal insufficiency to ensure that the desired concentration is achieved rapidly. For drugs typically administered without a loading dose, the presence of a prolonged half-life resulting from renal insufficiency may delay drug accumulation to steady state. In this setting, a loading dose (equal to the amount needed to reach steady state with normal renal function) is required.

Additional Considerations in Renal Insufficiency

Because of individual differences among patients, the approaches outlined earlier should be considered only initial approximations to prevent ineffective (too low) or toxic (too high) doses. For maintenance therapy, it is desirable to monitor blood levels to guide dosing.

If a metabolite of the drug is responsible for its effect or toxicity and the metabolite accumulates in the setting of renal failure, the drug level alone may not provide sufficient guidance for planning therapy. For example, the major metabolite of procainamide is *N*-acetylprocainamide, which has a toxicity similar to that of the parent drug but only modest antiarrhythmic activity. In the setting of renal failure, *N*-acetylprocainamide may accumulate dramatically because it is more dependent on renal elimination. Measurement of procainamide levels alone does not accurately assess either the levels needed for antiarrhythmic effect or the risk of toxicity.

Liver Disease

Although many drugs are biotransformed in the liver, it is not possible to make any general recommendations for drug dose adjustments in liver disease. In contrast to renal disease, no useful laboratory test is available on which to base dose adjustments. It has been suggested that if the liver's capacity to produce protein (reflected by albumin concentration and prothrombin time) is reduced significantly, the clearance of drugs metabolized by the cytochrome P-450 enzymes is probably reduced as well.

One special situation that can develop with chronic liver disease and may require dose adjustment is the portacaval shunt. This condition produces not only a potential hemodynamic alteration, leading to decreased hepatic blood flow and accompanying decreased clearance, but also a possible bypassing of the first-pass effect, resulting in higher concentrations of drug reaching the systemic circulation. Drugs with a large hepatic extraction that are typically administered orally (e.g., propranolol) may appear in the systemic circulation at higher, potentially toxic concentrations.

Hemodynamic Diseases

Decreased cardiac output and hypotensive conditions lead to decreased perfusion of the organs, including those responsible for eliminating drugs. As noted earlier with regard to primary kidney disease, the dose can be adjusted for decreased renal perfusion by the use of creatinine clearance. The effect of decreased hepatic blood flow on pharmacokinetics is more difficult to assess. For drugs that have a high hepatic extraction (e.g., lidocaine), decreased hepatic blood flow suggests a need for dose reduction.

Altered hemodynamics also may affect the distribution of selected drugs. Drugs that have a relatively large VD (e.g., lidocaine, procainamide, quinidine) may be affected by conditions leading to hypotension, such as shock, resulting in a decrease in the apparent VD. With a reduced VD, the loading dose of a drug should be reduced to avoid potentially toxic drug levels.

In general, in the setting of severely compromised hemodynamics, it is advisable to be conservative, avoiding potentially toxic loading and maintenance doses of drugs. Drug levels and the clinical status should be monitored closely, and drug doses should be adjusted as necessary.

APPROACH TO DRUG OVERDOSE

The pharmacokinetic principles discussed earlier can be used to determine the best approach to drug removal in the setting of a drug overdose, particularly if hemodialysis or hemoperfusion is contemplated. The major goal is to increase the overall clearance of the drug, removing a substantial fraction of the total body load of drug. Examination of the VD and clearance values can provide some guidance. For drugs with a large VD (e.g., digoxin; see Table 28-1), only a small amount can be removed because clearance affects only the amount of drug present in the plasma, and a large portion of the drug is outside the plasma compartment. Similarly, for drugs with high clearance values, hemoperfusion may increase the overall clearance only minimally and is not indicated. Table 28-2 provides data for determining whether hemodialysis is likely to be useful to remove several commonly prescribed drugs.

USING DRUGS IN THE ELDERLY

Administering drugs to the elderly is perhaps the most challenging area of adult therapeutics because of several factors: the increasing likelihood of multiple illnesses, often with multisystemic involvement; the need for these patients to take multiple drugs (often prescribed by different physicians); and the increasing probability of altered pharmacokinetics and pharmacodynamics. These factors together contribute to a significantly increased frequency of drug interactions and adverse drug responses in this group of patients.

Pharmacokinetic Changes with Age

These changes can be secondary to the general physiologic effects of aging, such as alteration in body composition, or to specific changes in pharmacokinetically important organs (e.g., kidneys, liver). The distribution of drugs tends to change dramatically with age, mainly because of changes in body composition. Most typical is the increase in total body fat, with the accompanying decrease in lean body mass and total body water. The concentration of plasma proteins may also change; in particular, albumin decreases as the liver ages. Changes in drug distribution are manifested as a change in the apparent VD. For water-soluble drugs that are not bound to plasma proteins, the apparent VD is reduced; in contrast, for lipid-soluble drugs, the VD is increased. Minimal changes in metabolism accompany aging, but these alone cannot account for altered pharmacokinetics.

Excretion can be altered in the elderly, and the clearance of many drugs is decreased. Cardiac output and blood flow to the kidneys and liver also may be decreased. Glomerular filtration rate may be reduced by 50%. Hepatic elimination of drugs is less affected, except for drugs with a high hepatic clearance (e.g., lidocaine). The elimination half-life of many drugs is increased with aging as a consequence of a larger apparent VD and a decreased hepatic or renal clearance (see Equation 5).

Pharmacodynamic Changes with Age

These changes are a result of changes in the responsiveness of the target organ. They require the use of smaller drug doses in the elderly, even if the pharmacokinetics are unchanged. This affects many drugs commonly used in the elderly; for example, antianxiety drugs and drugs from the sedative-hypnotic class may produce increased central nervous system depression in the elderly at concentrations that are well tolerated in younger adults. Similarly, anticoagulants (e.g., warfarin) may produce hemorrhage in the elderly at concentrations that are well tolerated in younger adults.

General Recommendations for Drug Use in the Elderly

- Clearance of drugs eliminated by the kidneys may be reduced by 50%.
- Drugs eliminated primarily by the liver typically do not require dose adjustments for age, except for drugs with high hepatic clearances, which may be affected by the age-related decrease in hepatic blood flow.
- Because of the potential for increased target organ sensitivity in the elderly, only the lowest effective dose should be used.
- Frequent reviews of the patient's drug history should be conducted, including both prescription and over-the-counter medications, keeping in mind the increased potential risk for drug interactions and adverse drug responses.

INTERACTIONS BETWEEN DRUGS

Because patients are typically treated with multiple agents, even for a single disease, the possibilities for drug interactions are great. Most clinically important drug interactions typically involve a drug with a low therapeutic index (e.g., warfarin) and an easily detectable pharmacologic effect (e.g., bleeding), such that a small increase in the amount of drug produces a significant effect (toxicity).

It is difficult to accurately assess the prevalence of drug interactions in either the inpatient or the ambulatory setting, particularly because no formal and comprehensive surveillance mechanism is available. The risk for drug interactions seems to be increasing, particularly for critically ill, hospitalized patients, who are frequently taking more than 10 medications.

There are basically two types of drug interaction: (1) pharmacokinetic drug interactions, caused by a change in the amount of drug or active metabolite at the site of action; and (2) pharmacodynamic drug interactions (without a change in pharmacokinetics), caused by a change in drug effect.

Pharmacokinetic Drug Interactions

Less Drug at the Site of Action

Decreased Absorption

The gastrointestinal lumen is perhaps the best example of an area where drug interactions can result in decreased drug absorption. Some commonly used drugs can illustrate this type of interaction. For many drugs, a physicochemical interaction prevents the drug from being absorbed. Drugs such as colestipol and cholestyramine (resins used to lower cholesterol and bind bile acids) can also bind other drugs present in the gastrointestinal lumen, including digoxin and warfarin. Because of the potential for many other drugs to be bound, it is generally recommended that other drugs not be administered within 2 hours of colestipol or cholestyramine. Another type of interaction occurs when metal ions (e.g., aluminum, calcium, and magnesium in antacids and iron in supplements to treat iron deficiency) form insoluble complexes with tetracyclines, which can act as chelating agents. Other commonly used medications that decrease absorption include kaolin-pectin suspensions to treat diarrhea. These medications can significantly inhibit the absorption of coadministered drugs (e.g., digoxin).

Drugs that are particularly susceptible to pH changes may have decreased absorption when they are administered with other drugs that either affect gastric acidity or alter the extent of exposure to low pH. Protein pump inhibitors or H_2-receptor antagonists may elevate gastric pH, which can inhibit the dissolution and subsequent absorption of drugs that are weak bases (e.g., ketoconazole). Medications that delay gastric emptying (e.g., belladonna alkaloids) can increase the degradation of a coadministered acid-labile drug (e.g., levodopa), resulting in decreased absorption.

Altered Distribution

Drugs that use the same active transport process to reach their site of action can compete at the level of transport, resulting in lower levels of drug reaching that site. The classic example of this type of interaction is the coadministration of guanidinium-type antihypertensives with tricyclic antidepressants, phenothiazines, and certain sympathomimetic amines (e.g., ephedrine), which block the effects of the antihypertensive drug.

Increased Metabolism

Many drugs (e.g., phenobarbital, phenytoin, ethanol, glutethimide, griseofulvin, rifampin) and toxic compounds (e.g., cigarette smoke, certain chlorinated hydrocarbons) can increase the hepatic metabolism of other drugs (e.g., corticosteroids, cyclophosphamide, cyclosporine, certain β-adrenergic blockers, theophylline, warfarin) by inducing the activity of the cytochrome P-450 mixed function oxidase (CYP) system.

More Drug at the Site of Action

Increased Absorption

Any drug that increases the rate of gastric emptying (e.g., metoclopramide) can potentially increase the absorption of acid-unstable drugs. Also, drugs that decrease intestinal motility (e.g., anticholinergics) may increase the absorption of drugs that are relatively poorly absorbed (e.g., digoxin tablets) by increasing the drug's contact time with the absorbing surface.

Altered Distribution

Drugs bound to protein are limited in their distribution (particularly to the site of action) and are not available for metabolism or excretion. Drugs can compete with each other for binding to plasma proteins, resulting in drug interactions. Sulfonamides can displace barbiturates bound to serum albumin, leading to increased levels of free barbiturates and possible toxicity.

Decreased Metabolism

One of the most impressive drug interactions is produced when one drug inhibits the metabolism of another, leading to the second drug's accumulation and a significant risk of toxicity. This type of interaction results when 6-mercaptopurine, an antileukemic drug with a low therapeutic index, is used with allopurinol, often administered to control hyperuricemia. The interaction may result in potentially life-threatening toxicity.

Some drugs can inhibit the metabolism of many other drugs. For example, cimetidine can inhibit the metabolism of diazepam, imipramine, lidocaine, propranolol, quinidine, theophylline, and warfarin. Amiodarone inhibits the metabolism of calcium-channel blockers, phenytoin, quinidine, and warfarin. Of particular importance with amiodarone is its half-life of 1 to 2 months; it continues to inhibit drug metabolism for several months after it has been discontinued.

Other drugs are notable because their metabolism is inhibited by a variety of different drugs. The metabolism of the commonly used anticoagulant warfarin is inhibited not only by cimetidine and amiodarone but also by many other drugs, including alcohol, allopurinol, disulfiram, metronidazole, phenylbutazone, sulfinpyrazone, and trimethoprim-sulfamethoxazole. Similarly, the metabolism of phenytoin is inhibited by chloramphenicol, clofibrate, dicumarol, disulfiram, isoniazid (slow acetylators), phenylbutazone, and valproic acid.

Although most of these examples involve enzymes that metabolize the drug in the liver, drug-metabolizing enzymes outside the liver also may be affected by certain drugs. The best-known example is monoamine oxidase, which can be affected by nonspecific monoamine oxidase inhibitors, resulting in the accumulation of catecholamines at multiple sites after their release in response to the eating of tyramine-containing foods such as aged cheese, aged or cured meats, and any spoiled meat, poultry, or fish.

Decreased Excretion

Drugs can compete for the active transporters present in the kidney. Most of these interactions involve the acid transporters. The best-known interaction is probenecid's inhibition of penicillin transport, leading to decreased penicillin clearance and thus higher plasma levels, an interaction that was used in the past to maximize penicillin therapy. A similar inhibitory effect on the renal excretion of methotrexate can be produced by salicylates, phenylbutazone, and probenecid. The active transport of basic drugs

(e.g., procainamide) can also be inhibited by other drugs (e.g., cimetidine, amiodarone).

Pharmacodynamic Drug Interactions

With pharmacodynamic interactions, drugs interact at the level of the receptor (target) or may produce additive effects by acting at separate sites on cells. An example of the first is the interaction of propranolol and epinephrine, which blocks β-adrenergic receptors; as a result, the α-adrenergic effects of epinephrine are unopposed. This undesirable interaction can result in severe hypertension.

Many examples exist of the additive effects of drugs. Aspirin, which can produce increased bleeding time by acting on platelets, can interact with warfarin, which affects clotting. The result is an increased risk of hemorrhage. Similarly, cardiac drugs, such as β-adrenergic blockers and calcium-channel blockers, have additive negative inotropic effects when they are coadministered, resulting in an increased risk of cardiac failure.

DIAGNOSIS AND PREVENTION OF DRUG INTERACTIONS

For a drug interaction to be recognized, the index of suspicion must be high whenever multiple drugs are used together. Because of the ever-increasing list of known and suspected drug interactions, it is impossible for a clinician to remember all or even many of the possible interactions.

Several clinical settings should raise concern about the possibility of drug interactions:

- The use of any drug with a low therapeutic index (Table 28-3) should be suspect.
- As the number of drugs being used concurrently increases, there is a disproportionately greater risk of drug interactions, particularly with more than 10 drugs.
- Critically ill patients who have multisystemic disease with compromised renal, hepatic, cardiac, or pulmonary function have an increased risk of drug interactions. This risk may be higher for patients with acquired immunodeficiency syndrome, who have an immunocompromised state and take a large number of drugs.
- Patients with various behavioral and psychiatric disorders (e.g., drug abusers taking a large number of prescription drugs as well as illicit drugs and alcohol) are at risk for drug interactions.

Another type of drug interaction that is becoming increasingly important is that between components of food (e.g., grapefruit juice) or natural products (e.g., herbs) and drugs. By inhibiting the intestinal cytochrome P-450 3A4 enzyme system, grapefruit juice can raise levels of drugs metabolized by this pathway (e.g., saquinavir, cyclosporine, verapamil) and result in toxicity or adverse drug effects.

Several steps can be taken to prevent drug interactions:

- When taking the medical history, it is important to document all drugs the patient is taking (and has recently taken), including prescription, over-the-counter, and other addictive drugs.
- It is desirable to minimize the number of drugs being taken by frequently reviewing the patient's drug list to ensure that each drug continues to be needed.
- There should be a high degree of suspicion when medications with a low therapeutic index known to have a high risk of drug interactions (see Table 28-3) are used.
- High-risk clinical settings, such as occur with critically ill patients, should raise the suspicion of adverse drug interactions.
- Adverse drug interactions should be considered in the differential diagnosis whenever any change occurs in a patient's course.

ADVERSE REACTIONS TO DRUGS

An adverse drug response (ADR) is an undesired effect produced by a drug at standard doses, which typically necessitates reducing or stopping the suspected agent and may require treatment of the noxious effect produced. Further harm may occur with continued or future therapy with the drug.

EPIDEMIOLOGY

The financial impact of ADRs is estimated to be more than $100 billion per year. The actual incidence of ADRs is difficult to quantify because many cases are either not recognized or not reported. Several large studies have shown that the incidence may approach 20% for outpatients (even higher for patients taking more than 15 drugs) and 2 to 7% for inpatients. The incidence of ADRs increases exponentially with more than four drugs. Meta-analyses of several prospective studies suggest that ADRs are now the third leading cause of death in hospitalized patients. It is clear from more recent surveys that a relatively small group of drugs (see Table 28-3) continues to be implicated in most of the reported ADRs. Current trends suggest that the incidence of ADRs is likely to increase as a result of more prescribed and over-the-counter medications being used.

ETIOLOGY

Most ADRs are caused by an exaggerated (but predictable) pharmacologic effect of the drug or by a toxic or immunologic effect of the drug or a metabolite (not typically expected).

Predictable Toxic Responses to Drugs

Exaggerated drug responses that cause adverse drug effects may be due to any condition that causes altered pharmacokinetics or pharmacodynamics (discussed earlier). There has been increasing interest in the discipline of pharmacogenomics, which explores the role of genetic factors in altered pharmacokinetics or pharmacodynamics and the resultant increased susceptibility to ADRs. There is now ample evidence that molecular changes in the genes coding for drug-metabolizing enzymes can account for the variability in pharmacokinetics and drug effects observed in population studies. There are now many examples of the role of pharmacogenomics in altered drug response and effect. Three of the best-studied examples are genetic polymorphisms associated with debrisoquine-sparteine, *N*-acetylation, and mephenytoin. Each is associated with autosomal recessive inheritance, and together they are responsible for the metabolism of approximately 40 drugs (Table 28-4). Individuals with autosomal recessive genes are typically "poor metabolizers," with potentially altered pharmacokinetics that result in elevated plasma drug concentrations and can lead to toxicity. Recent studies have focused on genomic alterations associated with the variability in response to some commonly used drugs. Thus, the variability of response to warfarin (Chapter 37) is now understood to be due to single nucleotide polymorphisms in the cytochrome P-450 2C9 (*CYP2C9*) and vitamin K epoxide reductase (*VKOR*) genes. These single nucleotide polymorphisms have a significant effect on warfarin dose requirements. Similarly, polymorphisms in transporter genes can have profound effects on the pharmacokinetics of statins (Chapter 213). A common genetic variant of the organic anion-transporting polypeptide 1B1 can reduce the hepatic uptake of many statins, increasing the risk of statin-induced myopathy. Also, it is now appreciated that genetically impaired adenosine triphosphate–binding cassette G2 transporter efflux activity can result in an increase in systemic exposure to various statins. Of particular importance to therapeutics is that the effects of these genetic polymorphisms differ, depending on the specific statin used. This provides a rational basis for an individualized approach to the use of lipid-lowering therapeutic agents.

A particularly impressive example occurs with certain cancer chemotherapy agents that have a relatively narrow therapeutic window and the potential to produce severe cytotoxicity (e.g., deficiency in dihydropyrimidine dehydrogenase activity can result in life-threatening toxicity after the administration of 5-fluorouracil). These defects typically are not recognized until the patient is given the drug. They are often described as "pharmacogenetic" syndromes.

Other genetic alterations do not affect metabolism specifically and do not produce a range of quantitative changes. These defects can produce "qualitative" defects and are often associated with structural defects. The classic example is glucose-6-phosphate dehydrogenase. Individuals who are deficient in this enzyme cannot tolerate the oxidative stress produced by some

TABLE 28-4 GENETIC POLYMORPHISMS OF DRUG-METABOLIZING ENZYMES

TYPE	PRIMARY DRUG EXAMPLES	OTHER DRUGS THAT ARE SUBSTRATES	INCIDENCE OF "POOR METABOLIZERS" IN WHITES (%)	ENZYME INVOLVED
Debrisoquine-sparteine polymorphism	Amitriptyline, codeine, tamoxifen	Antidepressants, antiarrhythmics, β-adrenergic receptor–blocking drugs, codeine, dextromethorphan, neuroleptics	5-10	Cytochrome P-450 IID6 (CYP2D6)
Mephenytoin polymorphism	Mephenytoin	Mephobarbital, hexobarbital, diazepam, omeprazole	4 (Japanese, Chinese, 15-20)	Cytochrome P-450 IIC (CYP2C)
N-acetylation polymorphism	Isoniazid, sulfadiazine	Hydralazine, phenelzine, procainamide, dapsone, sulfamethazine, sulfapyridine, aminoglutethimide, aminosalicylic acid, sulfasalazine	40-70 (Japanese, 10-20)	*N*-acetyltransferase (NAT2)
Methyl conjugation polymorphism	Catecholamines	L-Dopa, methyldopa	25-30	Catechol-*O* methyltransferase (COMT)

drugs, leading to hemolysis (Chapter 164). Drugs that can produce this clinical picture include aspirin, nitrofurantoin, primaquine, probenecid, quinidine, quinine, sulfonamides, sulfones, and vitamin K. Another similar defect is deficiency of methemoglobin reductase, which results in an inability to maintain iron in hemoglobin in the ferrous state, causing methemoglobinemia (Chapter 161) after exposure to oxidizing drugs such as nitrites, sulfonamides, and sulfones.

Unpredictable Toxic Responses to Drugs

Other toxic or immunologic ADRs are not predictable and are not obviously due to an increase in drug concentration (pharmacokinetic) or drug effect (pharmacodynamic). Unpredictable toxic responses include direct reactions between a drug and a specific organ (e.g., platinum-containing drugs, such as cisplatin, can produce direct toxicity in the kidney and the eighth cranial nerve). With other drugs, metabolism to an active intermediate must occur first. With a standard dose of acetaminophen, no untoward effects occur because the relatively small amount of reactive metabolite formed by oxidative metabolism is detoxified rapidly by reduced glutathione. In the presence of an overdose, the glutathione is depleted, and the remaining reactive metabolite can damage the liver. Understanding the mechanism of this toxicity has provided a rationale for treating acetaminophen overdose. Sulfhydryl-containing compounds (e.g., *N*-acetylcysteine), which can complex with the reactive metabolite, can be administered to reduce the amount of free toxic metabolite present, protecting the liver.

Immunologic reactions to drugs are generally not produced by the drug alone. Similar to other low-molecular-weight compounds (<1000 D), they are typically not antigenic themselves. When a drug or reactive metabolite combines with a protein to form a drug-protein complex, it can become antigenic, capable of eliciting an immune response.

Perhaps the most impressive form of drug allergy is anaphylaxis, which is due to an immunoglobulin E–mediated hypersensitivity. Many drugs from different classes have been shown to produce this type of drug allergy. The best-known example is the anaphylactic response produced by penicillin, which can occur after its administration by any route. Skin testing with penicillin G, penicilloic acid, or penicilloyl polylysine can identify patients at risk and should be performed in those with a suspected penicillin allergy who need treatment with penicillin. If the skin test result is positive, the patient must undergo desensitization before receiving penicillin. If the skin test result is negative, penicillin can be administered with caution.

DIAGNOSIS OF ADVERSE DRUG RESPONSES

Although many of the well-known adverse drug effects are due to a relatively small group of drugs, every drug has the potential to cause an ADR. A physician should always consider the possibility of an ADR in the differential diagnosis even if none has been reported previously for the particular drug. In earlier editions of this book, we provided a table listing many diverse clinical presentations associated with ADRs. The reader is now referred to the numerous websites providing more complete and up-to-date information on ADRs than can be detailed here. For example, *www.prosoftedc.com/aers/aers.php* allows one to monitor drug safety with unlimited access to up-to-date information from the Food and Drug Administration's Adverse Event Reporting System (AERS).

In many instances, it is readily apparent that a specific drug has produced an ADR, such as the appearance of a rash in an otherwise healthy patient who was recently prescribed a single drug (e.g., penicillin). In other cases, the effect produced by the drug may be difficult to discern from other disease states. In still other cases, the adverse effect may mimic the illness being treated (e.g., development of an arrhythmia in a patient being treated with an antiarrhythmic drug).

From a public health perspective, it is highly desirable to have a mechanism available to detect, catalog, and track the incidence and severity of ADRs not only for drugs at various stages of development but also for drugs that were approved earlier. The Food and Drug Administration tracks adverse drug events through a voluntary reporting program, MedWatch. Health care professionals are encouraged to report any adverse events or product problems on a one-page form that can be sent by mail, fax, or electronically to the Food and Drug Administration. Although various methods for surveying ADRs have been proposed, ultimately, the cooperation of alert clinicians and health care professionals must be encouraged.

PAIN

STEVEN P. COHEN AND SRINIVASA N. RAJA

Pain is ubiquitous in life, usually serving as a warning sign of impending or actual injury to the organism. As such, pain is older than humans, dating back to our most primitive ancestors. Pain is also a vital diagnostic clue for physicians. Physicians should be intimately familiar with pain because it is the most common symptom for which patients seek medical attention. According to the U.S. government's annual report on Americans' health, one in four adults suffered a day-long bout of pain within the past 30 days, and 10% suffer from pain every day. Among the various types of pain, back pain is the most common, followed by headaches and arthralgias. Spinal pain is the leading cause of disability in industrialized nations, with the economic costs exceeding $100 billion annually in the United States by some estimates. Special populations at particular risk for chronic pain include elderly people and individuals with physical and psychological morbidities. Several conditions characterized by chronic pain, such as irritable bowel syndrome, interstitial cystitis, fibromyalgia, and complex regional pain syndrome, are more prevalent in females than males.

DEFINITION

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." This definition recognizes that pain may be experienced in some circumstances in the absence of ongoing tissue damage, such as phantom pain after a healed amputation. One implication of this construct is the assumption that pain is always subjective; hence, a patient's report of pain should always be accepted at face value in the absence of evidence to the contrary.

PATHOBIOLOGY

Classification of Pain States

Multiple classifications have been used to describe pain states based on duration, anatomic source, or etiology. *Acute pain* usually results from injury or inflammation, has survival value, and may play a role in the healing process by promoting behaviors that minimize reinjury. In contrast, *chronic pain* is perhaps best construed as a "disease" that serves no useful purpose. Although there is no clear threshold at which acute pain transitions to a chronic state, it is generally accepted that pain persisting beyond the expected healing period is pathologic. In most cases, this period is between 3 and 6 months. The intensity of pain can be classified as mild (1 to 3), moderate (4 to 5), or severe (≥6 on a 0 to 10 numerical rating scale).

Somatic and Visceral Pains

Pain can originate from somatic or visceral structures. *Somatic pain* is well localized and generally results from injury or disease of the skin, musculoskeletal structures, and joints. *Visceral pain* arises from internal organ dysfunction and can result from inflammation, ischemia, occlusion of flow resulting in capsular or organ distension (e.g., renal stones, bowel obstruction, cholecystitis) or from functional pathology (e.g., irritable bowel syndrome). In contrast to somatic pain, visceral pain is usually diffuse and poorly localized, is often referred to somatic regions (e.g., myocardial ischemia radiating into the arm), and tends to be associated with exaggerated autonomic reflexes and greater emotional features.

Neuropathic, Nociceptive, and Mixed Pain

Pain can be etiologically classified as neuropathic, nociceptive, or mixed (Table 29-1). *Neuropathic pain* has been defined as pain resulting from disease or injury to the peripheral or central nervous somatosensory system. Common neuropathic pain states include postherpetic neuralgia, diabetic neuropathy, and radicular pain. *Nociceptive pain* usually results from an injury or disease affecting somatic structures such as skin, muscle, tendons and ligaments, bone, and joints. Pain associated with cancer can result from the tumor itself or can be a consequence of therapy (e.g., surgery, chemotherapy, and radiation therapy). In light of the often multiple different etiologies, advanced cancer pain is a typical example of a mixed pain state.

Dysfunctional Pain

There is a group of pain syndromes that have been characterized by amplification of pain signaling in the absence of either inflammation or injury (as in nociceptive pain) or damage to the nervous system (as in neuropathic pain). These conditions include pain states such as fibromyalgia, irritable bowel syndrome, and interstitial cystitis. The precise pathophysiologic mechanisms of pain in these disorders are unclear, although they share some features of neuropathic pain. Other chronic pain states, such as primary erythromelalgia and paroxysmal extreme pain disorder, are perhaps best described as hereditary channelopathies associated with mutations of the voltage-gated sodium channel Nav1.7. These mutations lead to increased excitability of nociceptive

TABLE 29-1 CLASSIFICATION AND PREVALENCE OF COMMON PAIN CONDITIONS

Neuropathic		*Nociceptive*		
PERIPHERAL	**CENTRAL***	**SOMATIC**	**VISCERAL**	**MIXED**
Peripheral neuropathy (1-3%)	Central post-stroke pain (8%)	Arthritis (25-40% in people >40 years)	Endometriosis (10% in women of reproductive age)	Headache (15% for migraine, 20-30% for tension-type)
Postherpetic neuralgia (annual incidence 0.1-0.2%)	Spinal cord injury (30-50%)	Myofascial pain (5-10%)	Irritable bowel syndrome (5-15%)	Cancer§ (lifetime prevalence 30-40%)
Chronic postsurgical pain (2-10% after surgery)	Multiple sclerosis (25%)	Fibromyalgia† (2-4%)	Interstitial cystitis (0.2-1% of women)	Low back pain‖ (point prevalence 10-30%)
Phantom limb pain (30-60% of patients with major limb amputation)	Parkinson's disease (10%)	Connective tissue disorders (0.2-0.5%)	Ulcers/gastritis/esophagitis (3-9%)	Neck pain‖ (annual incidence 20-30%)
Trigeminal neuralgia (0.01%)	Seizure disorder (1-3%)	Burn pain‡ (annual incidence of burns requiring hospitalization 0.01%)	Cholecystitis/appendicitis	Ischemic pain¶
Radiculopathy/spinal stenosis (3-10%)				
Complex regional pain syndrome (0.03%, 3-20% after orthopedic surgery)				
Nerve entrapment syndromes (e.g., carpal tunnel, thoracic outlet, meralgia paresthetica; 2-4%)				

*Prevalence rates represent proportion of patients with condition who develop pain.
†Some cases may represent a variant of central pain.
‡Third-degree burns often associated with neuropathic pain.
§Neuropathic pain occurs in 20-50% of cases and may occur secondary to tumor invasion, surgery, chemotherapy, and radiation treatment.
‖Neuropathic pain may accompany nociceptive pain in 10-35% of cases.
¶Typically nociceptive, but long-standing pain may result in ischemic neuropathy.

afferent fibers and ongoing activity in sensory neurons, resulting in spontaneous pain.

Pain Mechanisms

Pain results from activation of specialized peripheral receptors (*nociceptors*) by a noxious event (stimulus). These stimuli fall into one of three categories: *mechanical* (e.g., pressure, tumor growth, incision), *thermal* (e.g., hot or cold), or *chemical* (e.g., ischemia or infection). The stimulus is then converted into an electrical nerve signal (*transduction*), which is conveyed along the axons of thinly myelinated (A-delta) or unmyelinated (C) nerve fibers through specific pathways (*transmission*). *Modulation* refers to the attenuation of pain signals through intrinsic inhibitory activity within the peripheral and the central nervous systems before being perceived as an unpleasant sensation (*perception*). *Pathologic pain* is the result of injury- or disease-induced changes in the peripheral or central nervous system leading to alterations in the pain signaling process. One important example of pathologic pain from injury to the nervous system is *peripheral sensitization*. This form of pain is characterized by the development of spontaneous ectopic activity in injured nerves and dorsal root ganglion cells, as well as enhanced sensitivity to mechanical, thermal, or chemical stimuli. Recent studies have shown an important role for cytokines, such as tumor necrosis factor-α (TNF-α) and interleukins, released by macrophages and other inflammatory cells, in the peripheral sensitization process.

The prolonged and repeated activation of nociceptive afferent fibers produces *central sensitization*, a state of increased sensitivity of central pain signaling neurons. Activation of *N*-methyl-D-aspartate (NMDA) receptors by glutamate is thought to be an important mechanism for central sensitization. Recent studies indicate that in addition to functional changes in neurons, microglia and astrocytes may also play an important role in the central sensitization process. Other central neuroplastic changes that may contribute to neuropathic pain states include deafferentation hyperactivity that may occur after spinal cord or avulsion injuries, loss of large fiber afferent inhibition, reorganization of central connections of primary afferent fibers, and excitatory descending modulatory mechanisms. Central and, to a lesser extent, peripheral sensitization are considered to be the prime culprits responsible for pain induced by innocuous stimuli (*allodynia*), and increased pain to normally noxious stimuli (*hyperalgesia*), that are commonly observed in neuropathic pain states.

DIAGNOSIS

History

Similar to the work-up of any symptom, the evaluation of pain begins with a thorough history. One of the primary tenets of pain assessment is that subjective complaints should always be taken seriously. There is currently no diagnostic test that can measure pain or even ascertain its existence. The most promising techniques involve functional brain imaging that reflects cerebral metabolism. Presently, these techniques are research tools that have helped us understand that the brains of chronic pain patients undergo morphologic alterations such as a diminution in gray matter in the areas involved in pain perception. A comprehensive history should include the anatomic region of pain, its quality, exacerbating and relieving factors, temporal aspects, associated symptoms and signs (e.g., numbness or weakness), interference with activities of daily living, and response to current and prior treatments. The temporal aspects of pain can provide valuable clues to etiology and help guide treatment. Most cases of acute pain develop subsequent to a specific inciting event (e.g., surgery, trauma), whereas chronic pain conditions are usually more insidious in onset. Because acute pain tends to be self-limited and the relationship to a precipitant event is more tangible, it may be better tolerated and associated with fewer psychological sequelae.

The severity of pain can be measured through a variety of different rating scales. Some of the more common instruments include categorical scales, verbal and numerical rating scales (0 to 10), and the visual analogue scale, in which a 10-cm line is anchored on each side by two points designated as "no pain" and "worst possible pain." Because there are subtle differences between different types of scales, repeat assessments and response to therapy are ideally gauged using the same instrument. For young children and mentally incapacitated patients, the use of age-appropriate substitute scales or facial expressions has been validated.

Recent guidelines from experts across multiple specialties and sectors have concluded that pain scores represent only one component of pain management. Other important aspects of treatment include assessments of functional capacity (e.g., Oswestry disability index for back pain), psychological and emotional functioning (e.g., SF-36), satisfaction ratings, adverse treatment effects, and disposition (i.e., work status). It is therefore imperative that realistic goals are established, and individually tailored treatment regimens are developed to achieve these ends.

TABLE 29-2 CATEGORIZATION OF NEUROPATHIC AND NOCICEPTIVE PAIN

CLINICAL CHARACTERISTIC	NEUROPATHIC PAIN	NOCICEPTIVE PAIN
Etiology	Nerve injury or peripheral/central sensitization	Tissue or potential tissue damage
Descriptors	Lancinating, shooting, electrical-like, stabbing	Throbbing, aching, pressure-like
Sensory deficits	Frequent (e.g., numbness, tingling, pricking)	Infrequent and, if present, in nondermatomal or non-nerve distribution
Motor deficits	Neurologic weakness may be present if motor nerve affected	May have pain-induced weakness
Hypersensitivity	Pain frequently evoked with nonpainful (allodynia) or painful (exaggerated response) stimuli	Uncommon except for hypersensitivity in the immediate area of an acute injury
Character	Distal radiation common	Distal radiation less common; proximal radiation frequent
Paroxysms	Exacerbations common and unpredictable	Exacerbations less common and associated with activity
Autonomic signs	Color changes, temperature changes, swelling, and/or sudomotor (sweating) activity occur in one third to one half of patients	Autonomic signs uncommon in chronic nociceptive pain

Distinguishing between neuropathic and nociceptive pain can have important treatment implications (Table 29-2). Neuropathic pain is characterized by positive and negative symptoms. Negative symptoms, such as a loss of sensation, are usually the result of axon and neuron loss, whereas the positive symptoms reflect abnormal excitability of the nervous system. Numbness, tingling, and other symptoms suggestive of sensory dysfunction are strongly indicative of neuropathic pain, especially when they occur in a dermatomal or solitary nerve distribution. Descriptors such as "burning," "shooting," and "electrical" are more apt to be associated with neuropathic pain, whereas adjectives such as "squeezing," "throbbing," and "aching" tend to be strongly identified with nociceptive pain states such as acute inflammatory pain or arthralgias. Other positive symptoms observed in neuropathic pain states include pain evoked by normally innocuous stimuli (allodynia) and an exaggerated or prolonged pain to noxious stimuli (hyperalgesia or hyperpathia). Although neuropathic pain tends to be more intermittent than nociceptive pain, mechanical spinal pain is classically exacerbated by movement. As alluded to earlier, some conditions such as cancer may be characterized by aspects of both nociceptive and neuropathic pain.

The proper evaluation of the patient in pain includes a psychosocial history. Between one half and two thirds of chronic pain patients exhibit varying degrees of major psychopathology, with depression being the most common comorbidity, followed by anxiety disorders, somatoform disorders, and substance abuse. Many of these coexisting psychological conditions have been associated with poor treatment prognosis. People seeking chronic pain care may also be more likely to carry a concomitant axis II diagnosis (i.e., personality disorder). Patients with axis II diagnoses are more likely to be designated as "difficult patients," which can act as an additional barrier to effective treatment. Potential social factors that can negatively affect treatment should be identified, including low job satisfaction, secondary gain, and ongoing litigation. A focused psychosocial history that includes prior psychiatric diagnoses, suicidal ideation, work history, legal history, and substance abuse, is therefore essential in the formulation of a treatment plan.

Physical Examination

Examination of the patient in pain should encompass all bodily systems because pain is a frequent manifestation of systemic disease. A physical

examination finding by itself is almost never pathognomonic but usually functions to confirm suspicions garnered from the history and to select patients for imaging studies or invasive diagnostic testing. Unlike acute pain, *chronic pain is usually not associated with increased vital signs or facial grimacing.* Thorough neurologic and musculoskeletal examinations are particularly useful in evaluating pain. Sensory symptoms can precede other neurologic findings by months or weeks. The most common forms of neuropathy are associated with sensory deficits in a glove-stocking distribution, but other patterns occur as well (Chapter 428). Numbness in the distribution of a nerve root or single nerve strongly suggests neuropathic pain, but nondermatomal sensory changes can accompany nociceptive pain (e.g., fibromyalgia or arthritis) as well. Allodynia and hyperalgesia are hallmarks of neuropathic pain. Postural and gait abnormalities may be either causative factors for rheumatologic conditions (e.g., bursitis) or consequences of the underlying condition.

A careful evaluation of passive and active range of motion is useful because generalized and regional pain complaints are often accompanied by decreases in range of motion. Distinctions should be drawn between pain-induced and neurologic weakness, with the latter often occurring in conjunction with muscle atrophy or asymmetry in reflexes. Sometimes, reflex assessment is the only way to distinguish between a true neurologic condition and nonorganic etiologies; hence, deep tendon reflexes are a useful component of the pain exam.

Diagnostic Tests

Imaging has largely supplanted history and physical examination as the gold standard for diagnosing pathology, but is not without drawbacks. There is a poor correlation between findings on magnetic resonance imaging (MRI) and the intensity of spinal pain, with greater than 50% of asymptomatic individuals having abnormalities on lumbar, thoracic, and cervical films. Previous studies found that neither radiographs nor MRI studies affect treatment outcomes and are unlikely to affect decision making; in fact, redundant imaging can lead to unnecessary procedures. Absolute indications for MRI in patients with back pain are (1) serious or progressive neurologic deficits, (2) new-onset bowel and bladder dysfunction, (3) suspected metastatic disease, or (4) when referring patients for procedural interventions. The presence of "red flags" suggestive of more serious pathology (e.g., extremes of age, trauma history, immunosuppressed state, persistent fever, infection, or history of intravenous drug abuse) should also alert the practitioner to seek further evaluation. Electromyography and nerve conduction studies (Chapter 428) can be used to diagnose injury to large nerve fibers. However, because these studies are associated with significant false-negative and false-positive rates and are not sensitive in detecting impairment of small fiber (nociceptive afferent fibers) function, a normal neurophysiologic study does not rule out neuropathic pain. For small fiber neuropathies, a skin biopsy demonstrating decreased density of epidermal nerve fibers is a sensitive test.

For nonspinal pain conditions, MRI is ideal for detecting inflammation and soft tissue pathology, whereas computed tomography (CT) scanning is indicated for disease processes associated with bone destruction or ossification. The main advantages of ultrasound are that it is safe, is inexpensive, does not utilize ionizing radiation, and is relatively cheap.

TREATMENT

Rx

The goals of treatment should include elucidating the cause of pain and alleviating suffering. Consequently, the goal of pain treatment should not be limited to pain reduction but should encompass improving functional status, mood, and social interactions (i.e., quality of life). Chronic pain may result from diverse etiologies, including physical trauma, disease, infection, and therapies such as radiation, chemotherapy, and surgery. It has been argued that treatment should be mechanism based rather than etiology based, but at the present time, simple clinical tools to correlate symptoms and signs with mechanisms are lacking. Hence, treatment is primarily etiology based, or symptomatic. The future development and validation of diagnostic methods to identify mechanisms (e.g., intravenous infusion tests) may help develop novel target-specific pharmacologic agents.

Pain is a complex perceptual experience affected by a multitude of factors that include not only activation of nociceptors but also emotions (e.g., fear, anxiety), memory and cognition, social and cultural context, and expectations. Thus, it is not surprising that despite a paucity of studies evaluating a multidisciplinary approach to pain management, a strong consensus exists that this approach is beneficial.

Pharmacologic Therapies

Antipyretic Analgesics

Today, aspirin (Chapter 36) is the most widely used analgesic in the world. Along with its pharmacologic cousins, nonsteroidal anti-inflammatory drugs (NSAIDs) and the antipyretic drugs acetaminophen and phenacetin, this group forms the backbone of pharmacologic pain treatment. Antipyretic analgesics exert their antinociceptive effects by the inhibition of cyclooxygenase, the rate-limiting enzyme in the production of prostaglandins, which are lipid-based compounds that sensitize nociceptors and regulate inflammation. There are several pharmacologic distinctions between NSAIDs and their counterparts, phenazone and acetaminophen. Whereas NSAIDs act both centrally and peripherally, making them effective topical agents for nociceptive inflammatory conditions, the primary site of enzyme inhibition for acetaminophen is in the central nervous system. Acetaminophen is also a weaker analgesic than NSAIDs and is largely devoid of anti-inflammatory effects.

The main drawback of nonopioid antipyretic analgesics is their ceiling effect, which can render them ineffective as stand-alone agents for severe pain. For cancer pain, the World Health Organization treatment paradigm advocates adding opioids to an analgesic regimen uncontrolled by NSAIDs, not replacing them. NSAIDs may act synergistically with opioids and have proven opioid-sparing effects. It is well acknowledged that aspirin, NSAIDs, and acetaminophen are more effective in treating nociceptive than neuropathic pain, although a significant proportion of neuropathic pain sufferers regularly take NSAIDs.

The second major concern about nonopioid antipyretic agents is side effects. For NSAIDs, these include bleeding, gastrointestinal ulceration, renal toxicity, and an increased risk of cardiovascular events. Although the use of cyclooxygenase-2 selective inhibitors like celecoxib and rofecoxib may attenuate the risk of bleeding and ulcers, the risk of renal failure and cardiovascular events from these drugs remains a significant cause of morbidity and mortality. These risks are significantly increased in elderly patients and with polypharmacy. In view of its more favorable safety profile, acetaminophen is often considered a first-line therapy ahead of NSAIDs, even for pain conditions associated with inflammation.

Adjuvant Analgesics

Multiple evidence-based guidelines for the treatment of chronic pain states, particularly neuropathic pain, have been recently published. In general, these suggest that antidepressants and anticonvulsants should be the two first-line classes of medications for chronic neuropathic pain. Depending on the particular drug and condition, these medications have been demonstrated to provide significant pain relief above and beyond that observed with placebo in 20 to 40% of ideal pharmacologic candidates (i.e., number needed to treat is between 2.5 and 5 in randomized trials). Whereas opioids have shown similar efficacy for neuropathic pain, anticonvulsants and antidepressants carry a lower risk of serious adverse events (e.g., addiction) and long-term tolerance, rendering them preferable to opioids for long-standing noncancer pain (Table 29-3). In terms of efficacy, tricyclic antidepressants (TCAs) are superior to serotonin-norepinephrine reuptake inhibitors, which in turn are more effective than serotonin-specific reuptake inhibitors. Among the various TCAs, amitriptyline is the most studied but is probably comparable in efficacy to its metabolite nortriptyline and its cousin imipramine. However, the latter two drugs' more favorable side effect profiles (e.g., less sedation and anticholinergic activity) make them the preferred choices for neuropathic pain. In patients who cannot tolerate TCAs, serotonin-norepinephrine reuptake inhibitors such as duloxetine can be beneficial. In addition to neuropathic pain, antidepressants have also been shown to be effective in headache prophylaxis, chest pain, abdominal and pelvic pain, fibromyalgia, arthritis, and spinal pain.

Anticonvulsants are probably effective for neuropathic pain by virtue of their membrane-stabilizing-properties. Although anticonvulsant drugs may be slightly more effective than antidepressants for prototypical "lancinating-type" neuropathic pain, antidepressants may be more versatile in that they have proven benefit in myriad other pain conditions. Owing to their high efficacy and favorable side-effect profiles, gabapentin and its pharmacologic relative pregabalin are first-line agents for most forms of neuropathic pain. In addition to independent pain-relieving properties, these drugs may act synergistically with opioids, provide anxiolysis, and exhibit preemptive analgesic effects when administered before surgery.

When gabapentinoid drugs are ineffective or intolerable, alternative anticonvulsants that act through different cellular mechanisms such as lamotrigine and oxcarbazepine may be employed. For trigeminal neuralgia, carbamazepine remains the treatment of choice, although adverse effects, such as the risk of agranulocytosis, limit its utility for other conditions. Other classes of adjuvants that may be effective in certain contexts include topical creams (e.g., NSAIDs, capsaicin, lidocaine), *N*-methyl-D-aspartate antagonists (e.g., dextromethorphan), skeletal muscle relaxants (e.g., baclofen, cyclobenzaprine), cannabinoids, and antiarrhythmics (mexiletine). Topical lidocaine patches have been shown to reduce the pain and allodynia in patients with postherpetic neuralgia, and anecdotal evidence has suggested lidocaine may be useful in the treatment of certain types of back pain. Recently, a

TABLE 29-3 ADJUVANT ANALGESIC DRUGS FOR CHRONIC PAIN

DRUG	DOSAGE	INDICATIONS	ADVERSE EFFECTS	COMMENTS
TRICYCLIC ANTIDEPRESSANTS				
Amitriptyline, imipramine, desipramine, nortriptyline	10-150 mg/day	Peripheral neuropathy, postherpetic neuralgia, other types of peripheral neuropathic pain, central pain, facial pain, fibromyalgia, headache prophylaxis, irritable bowel syndrome, and chronic low back pain with or without radiculopathy	Sedation, dry mouth, confusion, weight gain, constipation, urinary retention, ataxia, cardiac conduction delay (QTc prolongation)	First-line agents for neuropathic pain and headache prophylaxis Secondary amine drugs (e.g., nortriptyline) have fewer side effects than tertiary amines (e.g., amitriptyline) Contraindicated in glaucoma
SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS				
Venlafaxine	75-225 mg/day	Peripheral neuropathy, headache prophylaxis	Sedation, dry mouth, constipation, ataxia, hypertension, hyperhidrosis	Dose adjustment in patients with renal dysfunction
Duloxetine	60-120 mg/day	Peripheral neuropathy, fibromyalgia, chronic back pain	Sedation, dry mouth, constipation, hyperhidrosis	U.S. Food and Drug Administration (FDA) approved for fibromyalgia and diabetic neuropathy Contraindicated in glaucoma
ANTICONVULSANTS				
Gabapentin	600-3600 mg/day	Peripheral neuropathy, postherpetic neuralgia, other types of peripheral neuropathic pain, central pain, pelvic pain, headache prophylaxis, radiculopathy, chronic postsurgical pain	Sedation, weight gain, dry mouth, ataxia, edema	First-line agent for neuropathic pain FDA approved for postherpetic neuralgia Effective preemptively for postoperative pain
Pregabalin	150-600 mg/day	Peripheral neuropathy, postherpetic neuralgia, central pain, fibromyalgia	Sedation, weight gain, dry mouth, ataxia, edema	First-line agent for neuropathic pain FDA approved for diabetic neuropathy, postherpetic neuralgia, fibromyalgia Effective preemptively for postoperative pain Same mechanism of action as gabapentin
Carbamazepine	200-1600 mg/day	Facial neuralgias, diabetic neuropathy	Sedation, ataxia, diplopia, hyponatremia, agranulocytosis, diarrhea, aplastic anemia, hepatotoxicity, Stevens-Johnson syndrome	First-line agent and FDA approved for trigeminal and glossopharyngeal neuralgia Contraindicated in patients with porphyria and atrioventricular conduction block
Topiramate	50-400 mg/day	Headache prophylaxis, chronic low back pain with or without radiculopathy	Sedation, ataxia, diplopia, weight loss, diarrhea, metabolic acidosis, kidney stones	First-line agent and FDA approved for migraine prophylaxis Often used as appetite suppressant
CORTICOSTEROIDS (SYSTEMIC)				
Prednisone	5-60 mg/day	Inflammatory arthritis, other inflammatory pain conditions (e.g., inflammatory bowel disease), traumatic nerve injury, complex regional pain syndrome	Myriad psychiatric, gastrointestinal, neurologic, and cardiac side effects; immunosuppression, weakness, edema, weight gain, elevated glucose, poor wound healing, others	Stronger evidence supports local (i.e., injection) administration More effective for acute pain Strong anti-inflammatory effects
MISCELLANEOUS				
Muscle relaxants	Variable depending on drug	Skeletal muscle spasm, acute spinal pain, temporomandibular disorder Baclofen effective for spasticity, dystonia, and trigeminal neuralgia	Sedation, ataxia, blurred vision, confusion, asthenia, xerostomia and other gastrointestinal effects, palpitations	First-line agents for acute back pain and skeletal muscle spasm
Lidocaine patch	1-3 patches every 12 hr	Postherpetic neuropathy, peripheral neuropathy, other types of neuropathic and possibly myofascial pain associated with allodynia	Minimal systemic side effects when applied appropriately	Second-line agent and FDA approved for postherpetic neuralgia
Capsaicin cream	0.025% applied 3 or 4 times per day	Postherpetic neuralgia, peripheral neuropathy and other types of neuropathic pain, chronic postsurgical pain, arthritis and other musculoskeletal conditions	Burning on application Minimal systemic side effects when applied appropriately	FDA approved for arthritis Second-line agent for postherpetic neuralgia and third-line agent for peripheral neuropathy Single application 8% patch providing up to 3 months of pain relief was recently approved for postherpetic neuralgia
Cannabinoids	Variable depending on drug and delivery route	Strongest evidence is for multiple sclerosis May be effective for peripheral neuropathy and other types of neuropathic pain spasticity	Myriad psychiatric, neurologic, and cardiac effects; xerostomia, abdominal pain, and other gastrointestinal effects	Fourth-line agent with narrow therapeutic index Modest analgesic effect comparable to codeine

high-concentration (8%) topical patch of capsaicin (the pungent chemical in chili pepper) has been approved for the treatment of postherpetic neuralgia. A single 1-hour application of the capsaicin patch can result in attenuation of pain for up to 12 weeks. Topical NSAIDs (e.g., diclofenac) have been shown to be effective in the short term for the treatment of osteoarthritis and other rheumatologic disorders and have been touted as having fewer adverse effects than systemic NSAIDs.

Opioid Analgesics

Opioid analgesics, such as morphine, oxycodone, hydromorphone, and methadone, are the cornerstone of treatment for cancer pain (Table 29-4). Several randomized studies have also demonstrated their usefulness in non-cancer pain conditions such as chronic osteoarthritis and neuropathic pain states. Maximizing the therapeutic effects of opioid analgesics requires careful attention to balancing the beneficial effects with the undesirable adverse effects. Understanding the clinical pharmacology of opioids, including their relative potency, duration of action, oral bioavailability, and pharmacokinetics, is essential for rational use (see Table 29-4). Their use for chronic pain management is limited primarily by their myriad side effects that include nausea, vomiting, constipation, sedation, itch, respiratory depression, and endocrine deficiency leading to sexual dysfunction and accelerated osteoporosis. Attentive treatment to opioid-induced side effects can facilitate dose titration, maximize analgesia, and minimize adverse effects. Aggressive management with stool softeners and agents that enhance bowel motility such as docusate, lactulose, and senna, can minimize constipation. Whereas most opioids are devoid of end-organ toxicity, an exception is meperidine. A metabolite, normeperidine, can accumulate after several days of treatment, causing myoclonus and anxiety; at higher concentrations, confusion, delirium, and seizures can ensue. Opioids that are predominantly renally eliminated, such as morphine, should be used with caution in patients with renal dysfunction. Two metabolites of morphine, morphine-6-glucuronide, which contains analgesic properties, and morphine-3-glucuronide, which may amplify pain in certain contexts, can accumulate in patients with renal dysfunction and are largely responsible for the adverse effects of morphine. Alternate drugs in such patients are fentanyl and methadone.

For treatment of acute pain (e.g., postoperative pain) or an acute exacerbation of chronic pain in hospitalized patients (e.g., sickle cell crisis), patient-controlled analgesia (PCA) provides a convenient means of administering opioids. Intravenous morphine, fentanyl, or hydromorphone is commonly administered using an infusion device designed to prevent overdose. With or without a basal infusion (which can be used to replace a sustained-release opioid in a patient who is NPO), the bolus dose, lockout time interval between doses, and the maximal dose per hour can be programmed in and adjusted based on clinical circumstances. PCA devices are safe and allow patients to control their pain management with less dependence on health care providers. Studies comparing PCA with conventional administration of opioids have generally found PCAs to be associated with better pain relief and higher satisfaction rates, albeit with larger amounts of medication consumed.

The long-term use of opioids can be associated with tolerance and physical dependence. Cross-tolerance among opioids is not complete, and a strategy that is often used when tolerance to an opioid is suspected is rotation to an alternate opioid drug. Although addiction (Chapter 33) to opioids when used

TABLE 29-4 FORMULATIONS, DOSAGES, AND PHARMACOLOGIC INFORMATION ON COMMONLY PRESCRIBED OPIOIDS

DRUG	EQUIANALGESIC DOSAGE (ORAL UNLESS SPECIFIED)	READILY AVAILABLE ROUTES OF ADMINISTRATION	DURATION OF ACTION	COMMENTS
Morphine	30 mg	IV, IM, PO, PR; SR formulation	3-6 hr for short-acting, 8-12 hr for SR	Reference standard for all opioids Renally excreted active metabolite
Oxycodone	20 mg	PO, PR; SR formulation	3-6 hr for short-acting, 8-12 hr for SR	Widely available in combination form with nonopioid analgesics; SR form popular among recreational users
Hydromorphone	3-6 mg	PO, PR, IV, IM	3-6 hr	Higher PO/IV conversion ratio than other opioids
Hydrocodone	30-60 mg	PO	3-6 hr	Wide variation in morphine equivalent dose Most commonly prescribed opioid in U.S. Typically used in combination form with nonopioid analgesic Formulations containing <15 mg hydrocodone are schedule III in U.S.
Methadone	2-20 mg	PO, PR, IV	6-12 hr for pain	Morphine: methadone conversion varies according to dose and length of opioid use, ranging from 2 : 1 to >20 : 1 in patients on very high doses Any physician with a schedule II DEA license may prescribe for pain May take 5-7 days to reach steady state due to extended half-life (i.e., accumulation) Electrocardiogram monitoring recommended with higher doses Other properties such as NMDA receptor antagonism and reuptake inhibition of serotonin and norepinephrine may slow the development of tolerance and increase efficacy for neuropathic pain
Fentanyl	12.5 µg/hr (TD) 800-1000 µg (TM) 200-400 µg (B)	TD, TM, B	72 hr for TD; 1 hr-2 hr for TM and B	TD, TM, and B formulations may be useful in patients with poor bowel function TD: wide variation in conversion ratios Delivery system may be associated with fewer gastrointestinal side effects TM and B: delivery systems associated with more rapid (10-min) onset than immediate-release oral opioids. U.S. Food and Drug Administration (FDA) approved for breakthrough cancer pain in opioid-tolerant patients
Codeine	200 mg	PO, PR	3-6 hr	Often used in combination with nonopioid analgesics Efficacy and side effects may be affected by rate of metabolism to morphine Popular as cough suppressant
Propoxyphene	200 mg	PO, PR	3-6 hr	Wide variation in morphine equivalent dose Often used in combination form with nonopioid analgesic Toxic metabolite may accumulate with excessive use, especially in elderly patients Weak antagonist at NMDA receptor
Meperidine	300 mg	PO, PR, IV	2-4 hr	Toxic metabolite may accumulate with excessive use, especially in patients with renal insufficiency Associated with tachycardia and hypertension May cause more "euphoria" than other opioids
Buprenorphine	0.4 mg SL	SL, PR, IV, TD	6-8 hr	Partial opioid agonist that may precipitate withdrawal in opioid-dependent patients Lower abuse potential, and fewer psychomimetic effects, than pure agonists Not readily reversed by naloxone Schedule III drug in U.S. Primary use of SL preparation is to treat addiction

B = buccal; IV = intravenous; NMDA = *N*-methyl-D-aspartate; PO = oral; PR = rectal; SL = sublingual; SR = sustained release; TD = transdermal; TM = transmucosal.

for the treatment of chronic pain is reported to be relatively uncommon, guidelines for responsible prescribing of opioids have been published as a monograph by the Federation of State Medical Boards. The critical suggested steps in the management of chronic pain patients with opioids include appropriate patient evaluation, creating and maintaining clear and detailed documentation, creating a function-based treatment plan with well-defined patient goals that include an exit strategy, obtaining a written patient-physician agreement that includes informed consent and patient education, periodic review that focuses on progress toward functional goals, and making specialist referrals when managing difficult patients. Diversion of opioids and the increasing abuse of prescription opioids, particularly in teenagers and young adults, is another growing societal concern (Chapter 33).

Tramadol and tapentadol comprise part of a new class of analgesic drugs that have a dual mechanism of action. Tramadol is a weak agonist and inhibits the reuptake of norepinephrine and serotonin. Along with the usual side effects associated with opioids, seizures have been reported with tramadol, and adverse drug interactions can occur in patients taking warfarin sodium (Coumadin) and selective serotonin reuptake inhibitors (SSRIs). Tapentadol also has a dual mode of action as a μ–opioid agonist and a norepinephrine reuptake inhibitor. Nausea, dizziness, constipation, and sedation are reported side effects of this drug. Tramadol is presently approved for moderate to moderately severe pain, whereas tapentadol, which is currently a schedule II drug in the United States, is approved for moderate to severe acute pain.

Butorphanol, nalbuphine, and pentazocine are opioid agonist-antagonist drugs that can antagonize the actions of μ–opioid agonists and can cause psychotomimetic effects owing to their actions on the κ-opioid receptor. These drugs should be used with caution, particularly in patients receiving other μ–opioid agonists. Buprenorphine, a partial agonist at the μ–opioid receptor and an antagonist at other opioid receptors, is available as a sublingual pill that is approved for the treatment of opioid addiction. A transdermal formulation is approved in Europe for the treatment of chronic pain.

Combination Therapies

Most clinical trials have studied the effects of individual drugs in specific chronic pain states. However, no one drug is universally effective, and often the drug only provides partial pain relief. In clinical practice, two or more drugs are often used in combination to achieve an additive beneficial effect or to decrease the adverse effects associated with the use of a single drug. The rational use of polypharmacy should include drugs that act at different sites in the pain signaling process or modulate different neurotransmitter systems, or both (Fig. 29-1). Although results are conflicting, a preponderance of recent randomized trials suggest that combination therapy with opioids and either anticonvulsants or antidepressants may be more effective than using either drug class as a stand-alone treatment.[3] Similarly, combining two adjuvant medication classes (e.g., gabapentin and nortriptyline) was recently shown to be more efficacious than giving either drug alone for neuropathic pain,[4] and combination treatment with pregabalin and celecoxib was found to be superior to monotherapy in a mixed population of patients with chronic low back pain.[5] Additional studies are needed to help develop guidelines for rational polypharmacy based on pain pathophysiology, mechanisms of action, and genetic medicine.

Psychological Treatment

The relationship between pain and psychopathology is complex. The lifetime prevalence rate of coexisting psychiatric illness in chronic pain patients ranges from 50% to upward of 80%. Between 30% and 60% of chronic pain sufferers experience symptoms of depression, making it the most common comorbidity. For anxiety disorders and substance abuse, the coprevalence rates are about 30% and 10 to 15%, respectively.

Viewed from a different perspective, the relationship is even more striking. More than 60% of patients with major depression and more than half of all patients with anxiety and substance abuse disorders experience moderate to severe chronic pain. Although it is widely acknowledged that disease states and injuries that result in chronic pain can predispose patients to depression, anxiety, and even self-destructive behavior, what is less commonly appreciated is the effect preexisting psychiatric conditions have on pain perception. There is a plethora of literature demonstrating that coexisting psychopathology is a strong predictor for the development of chronic pain after an acute, traumatic event (e.g., back pain episode, surgery, motor vehicle crash).

It is necessary to screen all pain patients for psychological conditions that can adversely affect treatment (Table 29-5). Not only major psychiatric conditions such as depression and generalized anxiety but also maladaptive behaviors and secondary diagnoses such as somatization disorder and poor coping skills can negatively influence treatment. Psychological screening is mandated for pain patients being considered for neuromodulation (e.g., spinal cord stimulation), and many spine surgeons will defer surgery until major psychiatric issues are adequately addressed.

Relaxation techniques such as biofeedback, self-hypnosis, and guided imagery have proved effective in a wide array of acute and chronic pain conditions but may be especially useful in those with high levels of anxiety. Cognitive behavioral therapy is a highly structured form of psychotherapy predicated on the replacement of negative thought patterns and behaviors with more positive, constructive ones. These therapies may enhance the modulation of afferent pain signals. Ideal candidates include educated, motivated patients in whom distorted thinking (e.g., "catastrophization") and counterproductive behaviors serve to amplify pain behavior. In patients with personality disorders and ingrained maladaptive behaviors, long-term psychotherapy may be necessary.

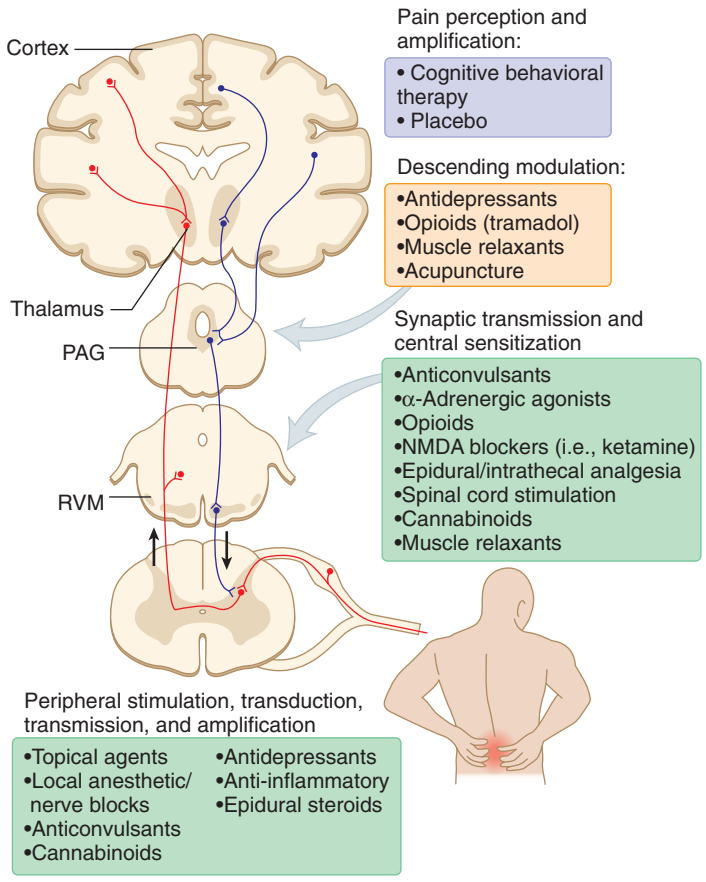

FIGURE 29-1. Rational choice of combination therapies for pain should be based on the mechanisms of drug actions. Combining drugs with disparate actions can have additive or synergistic analgesic effects and minimize adverse effects. NMDA = *N*-methyl-D-aspartate; PAG = periaqueductal gray; RVM = rostral ventromedial medulla.

TABLE 29-5 PSYCHOSOCIAL FACTORS ASSOCIATED WITH CHRONIC PAIN

Multiple pain complaints
Poor job satisfaction/low pay
Inadequate coping skills
Fear-avoidance behavior
Manual labor/physically stressful job
Obesity
Somatization
Smoking
Low baseline activity levels
Ongoing litigation
Low education level
Greater baseline disability
Anxiety
Depressed mood
Emotional distress

Interventional Therapies: Nerve Blocks, Neuromodulation, and Neurosurgery

Nerve Blocks

Nerve blocks and injections may be done for therapeutic, diagnostic, and sometimes prognostic purposes (i.e., to select candidates for surgery or radio

frequency denervation). Mechanistically, injections performed with local anesthetic may work by releasing entrapped nerves, enhancing blood flow, and interrupting processes involved in central sensitization (i.e., "breaking the cycle of pain"). Additional benefits of adding corticosteroid to local anesthetic include blocking the inflammatory cascade, suppressing ectopic discharges from injured nerves, and inhibiting the synthesis of prostaglandins, some of which serve to sensitize nociceptors.

Nerve blocks are almost never a panacea for noncancer pain, but in appropriate candidates, blocks may provide intermediate-term pain relief, facilitate rehabilitative therapy, and improve quality of life for several weeks to months. Translating this relief into long-term improvement inevitably necessitates addressing the underlying etiologies and predisposing factors, which often entails physical therapy, psychotherapy, and rehabilitation. Injections that can afford benefit in well-selected individuals include trigger point injections with local anesthetic for myofascial pain and nerve blocks with corticosteroid for entrapment syndromes (e.g., carpal tunnel syndrome, occipital neuralgia). Among spinal injections, the strongest evidence is for epidural steroid injections in patients with radicular pain of less than 6 months' duration. Neurolytic procedures, such as celiac plexus neurolysis with alcohol or phenol, have been shown to provide significant pain relief lasting several months in patients with pain associated with cancer of the pancreas, liver, and gastrointestinal tract.

Spinal Cord Stimulation

Spinal cord stimulation is an effective, minimally invasive neuromodulatory technique for managing a variety of chronic pain states refractory to more conservative measures. It was developed based on the gate-control theory, which postulates that activation of peripheral sensory A-fibers can attenuate pain signaling by slower-conducting pain C-fibers. Common indications include failed back surgery syndrome, complex regional pain syndromes, and outside of the United States, ischemic pain.

Surgery

Surgical interventions are often advocated in chronic pain patients who have failed more conservative measures, but surgery is fraught with the same limitations as nerve blocks. A traumatic neuroma is an inexorable consequence of cutting or burning a nerve, formed as a result of unregulated and disorganized nerve regeneration. Neuromas have been shown to fire ectopic pain signals and are often quite painful. Hence, neurolytic procedures are rarely successful in the long-term treatment of neuropathic pain. Part of the challenge in deciding when operative therapy is indicated revolves around the difficulty involved in establishing a causative relationship between the targeted pathology and pain. Roughly 10% of women of reproductive age have endometriosis, but many patients with endometriosis have minimal symptoms, and pelvic pain is a frequent occurrence in young females with no detectable pathology. With respect to inguinal hernia repair and spinal decompression, the incidence of chronic postsurgical pain is inversely correlated with the size of the bowel and disc herniation, respectively. This illustrates that in many of these individuals, the targeted pathology may not have been the primary cause of symptoms. On a similar note, scar tissue is a predictable sequela of surgical treatment, but lysis of adhesions is only infrequently associated with long-term symptom palliation because of the high recurrence rate and absence of any means to correlate the presence of adhesions with pain. Not surprisingly, surgery done solely to remove a painful body part (e.g., hysterectomy, orchiectomy) rarely results in long-term benefit.

Back Pain

Back pain is the leading cause of disability in people younger than 45 years in the industrialized world and thus deserves separate mention when discussing interventional therapies. In patients who present with serious spinal pathology (primarily infection, tumor, and trauma), decompression, stabilization, and fusion can be highly beneficial, but outcomes are strongly dependent on the primary pathology and patient. Decompression procedures done for spinal stenosis or radiculopathy are also effective for short-term relief, but the benefits diminish with time.[6,7] With respect to fusion or disc replacement done for axial pain associated with common degenerative changes, less than 40% of patients can expect a highly functional outcome.

Physical Treatments

The use of "physical" therapies to provide pain relief and enhance function forms a cornerstone in the multimodal approach to the patient with pain. Physical therapists evaluate, educate, and provide minimally invasive and noninvasive procedural interventions to patients to help prevent and alleviate the pain and dysfunction associated with physical and mental maladies. These interventions include both addressing causative mechanisms of pain (e.g., core strengthening, correcting gait and postural abnormalities) and providing treatments (e.g., ultrasound, hot and cold packs, joint manipulation).

Exercise has been used for decades as a treatment for chronic pain and as a means to prevent injury. Exercise may work through a variety of mechanisms, including enhancing blood flow, releasing endorphins, exerting anti-inflammatory effects, activating descending inhibitory pathways, and improving sleep and mood. Whereas the largest body of research has been conducted in patients with spinal pain, benefits have also been demonstrated in those with fibromyalgia, headaches, arthritis, neuropathic pain, and cancer.

Complementary and Alternative Therapies

Physicians are referring patients for complementary and alternative medical (CAM) treatments with increasing frequency, with utilization rates exceeding one third for certain conditions. CAM therapies have been used to treat myriad pain conditions, including cancer and noncancer pain and both neuropathic and nociceptive conditions (Chapter 38). Some of the most popular and studied CAM modalities are acupuncture, chiropractic, yoga, and dietary supplements, all of which have been shown in clinical trials to reduce pain and improve functional capacity in certain contexts. However, the effect size tends to be modest for these treatments, and there is little evidence to support the superiority of any one "proven" modality over another.

Pain Management in Older Persons

Older adults often have varied and multiple pain conditions that exist with other comorbidities. Pharmacologic management of pain in this population can be challenging because of the potential for drug-drug and drug-disease interactions. The potential for drug-related adverse effects is the basis for the popular recommendation of "start low and go slow" in the titration of analgesic drugs. The potential interaction between anticoagulants, such as warfarin and aspirin, and NSAIDs can result in an increased risk for bleeding. Age-related decrease in hepatic blood flow and decreased first-pass effect can result in higher bioavailability of opioids, such as morphine. Significant interactions between analgesic drugs metabolized hepatically by CYP2D6, such as codeine, hydrocodone, oxycodone, tramadol, and antidepressants, may result in decreased metabolism and increased toxicity. Several drugs used for the management of chronic pain and their active metabolites, such as duloxetine, gabapentin, pregabalin, oxycodone, and tramadol, are primarily renally eliminated. Their dose should be adjusted accordingly. An updated guideline for the pharmacologic management of persistent pain in older persons based on a synthesis of the best available evidence has been recently published.

FUTURE DRUGS AND PREVENTION OF PAIN

Much research is being done to develop new routes of drug administration, abuse-deterrent opioids, and novel nonopioid drug treatments, which can optimize outcomes and reduce risks and side effects for pharmacotherapy. Two other areas ripe for investigation are the development of drugs that exploit the unique genetic makeup of pain patients, and refining selection criteria for various therapies. The conceptual appeal of these and other endeavors is that treatment tailored to individuals is likely to result in greater benefit and less risk than the "shotgun" approach to pain treatment that is too often used.

Regenerative therapies, which seek to facilitate the body's ability to repair, replace, restore and regenerate diseased or damaged tissue, is another frontier in pain medicine. These treatments are currently in preliminary stages of development but may someday be used to treat central, joint, and spinal pain.

Finally, identifying patients at high risk of developing pain and employing strategies to either prevent pain or minimize the disease burden represent other areas that have been henceforth underinvestigated. In patients at high risk for chronic postsurgical pain (e.g., young patients with preexisting pain and psychological comorbidities), these measures might include the use of preemptive analgesics, such as NSAIDs and anticonvulsants, and employment of surgical techniques associated with less trauma. For patients with musculoskeletal complaints, this might entail educational initiatives, extensive rehabilitation, fall-reduction classes, and increased reimbursement for walking aids and wheelchairs.

30 BIOLOGY OF ADDICTION

STEVEN E. HYMAN

DEFINITION

Drug addiction is defined as compulsive substance use despite serious negative consequences. Harmful drug use and addiction are significant contributors to medical morbidity and mortality both directly as a result of the toxic effects of abused drugs and indirectly through accidents, violence, nonsterile needle use, and other health hazards. By far the greatest contributors to illness and death are the widely used legal drugs, tobacco (Chapter 31) and alcohol (Chapter 32), although illegal addictive drugs and abused prescription drugs (Chapter 33) also exact a significant toll. In addition, addiction creates enormous burdens on society by impairing the function of the addicted person in multiple life roles, disrupting families and neighborhoods, and motivating crime.

Compulsive use, the cardinal feature of addiction, means that the affected person cannot control substance use for a significant period of time, despite powerful reasons to do so such as drug-related health problems, drug-associated arrest, or the threat of losing one's job or spouse. In the clinic, addiction can be remarkably frustrating to treat: drug seeking and administration are apparently voluntary behaviors that an otherwise sentient person seems unwilling to control. Even after significant efforts have been exerted to get an addicted patient into drug treatment, relapse is common, even long after the last withdrawal symptom has cleared. Relapses are often precipitated by stress or by reminders of drug use ("cues") that may range from familiar drug use contexts (such as smoking after a meal), to interactions with drug-using friends, to the smell of marijuana or tobacco smoke, to bodily feelings previously associated with drug-seeking (interoceptive cues). Cellular and molecular studies of drug action, animal models of drug use, and noninvasive human neuroimaging studies are providing significant insights into the neurobiology underlying compulsive drug taking and its persistence. Other important frontiers of research include the human genetics of addiction risk and more recently, the neurobiology of what have been called "behavioral addictions," such as compulsive gambling.

Drug users may repeatedly take drugs in order to gain pleasure or escape from negative feelings, including the aversive feelings that may occur when drugs wear off. As a result of repeated drug administration over time, drug receptors and their downstream signaling pathways (Table 30-1) are excessively stimulated and may thus undergo homeostatic adaptations. These adaptations can produce tolerance (the need for increasing drug doses to achieve desired affects) or dependence (revealed by withdrawal symptoms between drug doses or with drug cessation). Both tolerance and dependence can contribute to ongoing drug use and to dosage increases; however, neither tolerance nor dependence explains compulsive use. First, tolerance and dependence occur not only with repeated use of many addictive drugs (e.g., heroin), but also with many nonaddictive drugs (e.g., bronchodilators, nitrates, selective serotonin reuptake inhibitor [SSRI] antidepressants). Second, some highly addictive drugs such as cocaine may produce little dependence and withdrawal in some individuals who nonetheless exhibit compulsive use. Finally, if dependence and withdrawal were necessary factors in addiction, the phenomenon of late, post-detoxification relapse would not be the major clinical problem that it is. Although these forms of homeostatic adaptation play a role in addiction, as will be described, other types of plasticity within the nervous system are more significant.

The term *dependence* was selected to signify *addiction* within the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association (DSM-IV) presumably because the term *addiction* was thought to be stigmatizing. This choice unfortunately has contributed to the confusion of physiologic dependence (the type of adaptation described previously) with addiction by physicians and patients alike. This confusion creates unnecessary obstacles to the treatment of many conditions, including cancer pain, anxiety disorders, and depression.

RISK FACTORS FOR ADDICTION

Only a minority of individuals who use drugs go on to become addicted. The best-established risk factors for addiction are male sex and family history. Across countries and cultures, males have a greater risk for both heavy drug use and addiction with risk ratios in the range of 1.4 : 1 to 2 : 1. In recent years, however, the sex ratios have narrowed in many countries, especially for tobacco use and alcohol.

Genes play the preponderant role in familial risk as evidenced by twin and adoption studies. Twin studies consistently show higher rates of concordance for heavy drug use and addiction within monozygotic twin pairs than within dizygotic twin pairs. Adoption studies that have been performed in several Scandinavian countries and in the United States have focused mostly on alcoholism. These studies demonstrate that individuals adopted early in life

TABLE 30-1 PROPERTIES OF ADDICTIVE DRUGS

DRUG	NEUROTRANSMITTER	DRUG TARGET	EFFECT AFTER BINDING
Opiates (morphine, heroin, oxycodone)	Endorphins	μ and δ opioid (agonist)	Activate G_i/G_o Activate K^+ channels
Psychostimulants (cocaine, amphetamines)	Dopamine (DA)	Dopamine transporter (DAT)* (antagonist)	Increase synaptic DA; stimulate presynaptic and postsynaptic DA receptors
Nicotine	Acetylcholine	Nicotinic acetylcholine receptors (nAChRs) (agonist)	Stimulate cation channel (may desensitize)
Alcohol	γ-Aminobutyric acid (GABA) Glutamate	$GABA_A$ receptor (agonist) *N*-methyl-D-aspartate (NMDA) receptor (antagonist)	Activate Cl^- channel Inhibit Ca^{2+} entry
Marijuana (Δ^9-tetrahydrocannabinol)	Anandamide	Cannabinoid CB_1 (agonist)	Activate G_i/G_o
Phencyclidine, ketamine		NMDA receptor channel (antagonist)	Inhibit Ca^{2+} entry

*The psychostimulants also interact with the norepinephrine and serotonin transporters, but under normal conditions, it is the DAT that is critical for rewarding and addictive properties. Unlike cocaine, amphetamines enter dopamine through the DAT and interact with a second target, the vesicular monoamine transporter (VMAT), to release DA into the cytoplasm and thence, through the DAT, to release it into the synapse.

Adapted from Hyman SE, Malenka RC, Nestler EJ. Neural mechanisms of addiction: the role of reward-related learning and memory. *Annu Rev Neurosci.* 2006;29:565-598.

tend to resemble their biologic rather than their adoptive parents with respect to patterns of alcohol use.

Although genes clearly play a significant role in vulnerability to addiction, few of the specific genetic variants that confer risk have been identified with certainty. Like all common neuropsychiatric disorders, addiction risk is highly genetically complex; there is evidence from linkage and association studies for contributions by a large number of genetic variants of relatively small effect. Large genome-wide association studies and other applications of modern genomic methods are continuing. However, the task of gene identification is also complicated by the challenges of phenotype definition. There are no objective medical tests with which to make the diagnosis, and there may be independent genetic and nongenetic risk factors for different stages of substance use disorders such as drug experimentation, addiction, and treatment responsiveness. Moreover, twin and family studies suggest that there may be both shared and unshared genetic risk factors underlying different drug preferences. As in other genetically complex disorders, it is hoped that with the identification of multiple risk-conferring variants, systems biology approaches can be brought to bear that will identify biochemical pathways involved in pathogenesis and suggest potential treatment targets.

REWARD CIRCUITRY: THE NEURAL SUBSTRATE OF ADDICTION

The survival and perpetuation of species require that animals, including humans, learn to predict threats and also learn the circumstances under which they can obtain food, water, shelter, and opportunities for mating. Neural circuits that have been highly conserved in evolution underlie these survival functions. A "fear circuit" centered on the amygdala regulates responses to threats, and a "reward circuit" centered on dopamine-releasing neurons that project from the ventral tegmental area (VTA) of the midbrain to the nucleus accumbens (NAc), prefrontal cortex, and other forebrain structures (Fig. 30-1) controls the pursuit of positive survival goals or "rewards." A simple operational definition of reward is a stimulus that elicits approach and consummatory behaviors.

Based on lesioning and physiologic studies in animals and more recently imaging in humans, the NAc (see Fig. 30-1), especially its outer region, called the *shell*, has been shown to play a necessary role in assigning motivational properties (desire, incentive salience) on rewards and to the stimuli that predict them. Thus, for example, in rat and mouse models, an intact NAc is required if the animal is to learn to work (e.g., lever pressing) to obtain natural rewards, such as palatable foods, or to learn how to self-administer drugs such as cocaine. Once an animal learns how to obtain a reward, and the relevant behaviors become ingrained, reward seeking no longer depends on the NAc and is supported by the dorsal striatum (called the *caudate* and *putamen* in humans), the brain structure that underlies well-learned behaviors and habits.

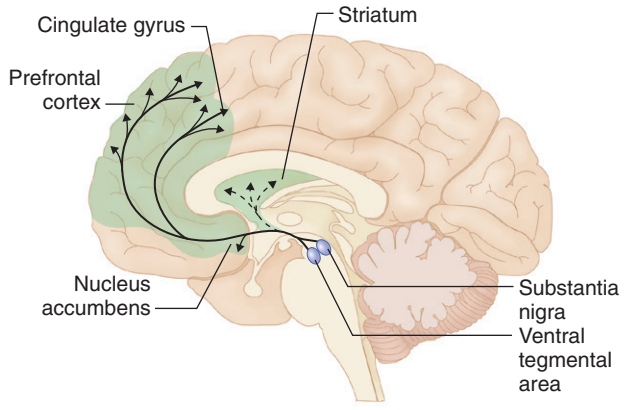

FIGURE 30-1. Brain reward circuits. The major dopaminergic projections to the forebrain that underlie brain reward are shown superimposed on a diagram of the human brain: projections from the ventral tegmental area to the nucleus accumbens, amygdala (not shown), hippocampus (not shown), and prefrontal cerebral cortex. Also shown are projections from the substantia nigra to the dorsal striatum (caudate and putamen and related structures) that play a role in habit formation and other deeply ingrained motor behaviors, including cue-dependent drug-seeking and self-administration. (From Hyman SE, Malenka RC, Nestler EJ. Neural mechanisms of addiction: the role of reward-related learning and memory. *Annu Rev Neurosci.* 2006;29:565-598.)

Under natural conditions, speed and efficiency in gaining food, water, and shelter improve the probability of survival. Thus, a critical role of reward circuitry is to facilitate the rapid learning of cues that predict the proximity of reward and of the behaviors that maximize the chances of successfully obtaining it. Once learned, predictive cues automatically activate cognitive, physiologic, and behavioral responses aimed at obtaining the predicted reward. In the laboratory, the simplest example of reward-related learning is classic (or pavlovian) conditioning in which a neutral stimulus, such as the sound of a bell, is reliably paired with a natural reward (an unconditioned stimulus) such as food. The sound of the bell quickly becomes a learned (conditioned) stimulus that henceforth activates physiologic and behavioral preparedness to obtain and consume the food.

The neurotransmitter dopamine, released from VTA neurons in the NAc, plays the key (albeit not the only) role in binding rewards and reward-associated cues to adaptive reward-seeking responses. In animals, implanted electrodes can record firing of dopamine neurons; microdialysis catheters and electrochemical methods can be used to detect dopamine that has been released from presynaptic neurons. In humans, positron emission tomography (PET) permits indirect measures of dopamine release by observing the displacement of a positron-emitting D_2 dopamine receptor ligand previously bound to receptors following a stimulus or pharmacologic challenge. Using such methods in multiple paradigms, it has been well established that natural rewards cause firing of VTA neurons and dopamine release in the NAc and other forebrain regions. When dopamine action is blocked, whether by lesioning dopamine neurons, blocking post-synaptic dopamine receptors, or inhibiting dopamine synthesis, rewards no longer motivate the behaviors necessary to obtain them.

New insights into the role of dopamine have emerged from studies of patients with Parkinson's disease (PD). PD results from the death of midbrain dopamine neurons; however, neurons within the substantia nigra (SN), which project to the caudate and putamen, are more severely affected than neurons within the VTA. Patients are generally treated with L-DOPA, a dopamine precursor, but as the disease progresses, other drugs may be needed, including selective D_2 dopamine receptor agonists. Relevant to this discussion is that a minority of patients treated with D_2 dopamine receptor agonists develop new risky, goal-directed behaviors such as compulsive gambling or compulsive shopping. These behaviors generally cease when the drug is withdrawn. It is thought that dopamine receptor agonists produce therapeutic effects on motor behavior in the more fully denervated caudate and putamen but combine with endogenous dopamine from preserved VTA neurons to overstimulate the NAc and other components of reward circuitry. These observations not only underscore the role of dopamine in motivation and reward seeking, but also suggest that what have been called *behavioral addictions* such as compulsive gambling share neural substrates with drug addiction.

Electrophysiologic recordings from nonhuman primates and functional magnetic resonance imaging (fMRI) studies in humans have converged on new views of how dopamine acts. Contrary to earlier ideas, dopamine does not appear to function as a neural representation of pleasure; rather, it serves as a learning signal in diverse forebrain circuits that are involved in responding to rewards. Dopaminergically innervated circuits underlie such functions as connecting reward-related stimuli to desire (NAc), learning and automatizing new motor behaviors (caudate and putamen), response selection, and relative valuation of experiences (orbital prefrontal cortex). Other neurotransmitters, perhaps endogenous opioid peptides, may be involved in hedonic responses (i.e., signaling pleasure). In this regard, it is noteworthy that nicotine, which is highly addictive—and causes dopamine release—does not produce significant euphoria of the sort produced by cocaine or heroin.

Much evidence suggests that the precise pattern of dopamine neuron firing, and the resulting synaptic release of dopamine in forebrain circuits, act to shape behavior so as to maximize future reward. In a basal state, dopamine neurons have a slow tonic pattern of firing. When a reward is encountered that is new, unexpected, or greater than expected, there is a phasic burst of firing of dopamine neurons causing a transient increase in synaptic dopamine. When a reward is predicted from known cues and is exactly as expected, there is no change from the tonic pattern of firing, that is, no additional dopamine release. When a predicted reward is omitted or less than expected, dopamine neurons pause their firing to levels below their tonic rate. Phasic increases in synaptic dopamine signify that the world is better than expected, facilitate learning of new predictive information, and bind the newly learned predictive cues to action.

PROPERTIES OF ADDICTIVE DRUGS

Addictive drugs are chemically diverse and interact with different molecular targets in the nervous system (see Table 30-1). They also exhibit significant differences from each other in many of their physiologic and behavioral effects. For example, cocaine and amphetamines are stimulants; they increase arousal, may cause anxiety, and at lower doses enhance cognitive performance. Alcohol is a depressant, is anxiolytic at low doses, and degrades cognitive performance. Heroin and other opiates are analgesic and cause drowsiness, constipation, and pupillary constriction. The shared behavioral effect of all addictive drugs is the liability, in vulnerable individuals, of causing compulsive use. The shared pharmacologic property that is required to cause addiction is the ability to increase levels of synaptic dopamine in the forebrain. For example, cocaine blocks the dopamine uptake transporter (DAT) that normally clears dopamine from synapses. Amphetamines cause reverse transport of dopamine into synapses through the DAT. Opiates, nicotine, alcohol, and cannabinoids cause dopamine release, acting by different initial mechanisms to release VTA neurons from resting inhibitory control.

Natural rewards, such as food or sexual opportunities, regulate the firing of dopamine neurons through highly processed sensory information, both external and interoceptive. Addictive drugs short-circuit this kind of information processing by acting directly on receptors and cells that regulate VTA dopamine neurons. Acting by such direct pharmacologic mechanisms, addictive drugs may produce greater quantities of synaptic dopamine over longer times than natural rewards. In addition, addictive drugs provide a grossly pathologic learning signal by occluding pauses in dopamine neuron firing even when drug use proves less pleasurable than expected or even aversive. For example, when the inhalation of a smoker causes painful coughing, it might seem that the brain would signal an experience that is worse than expected with a resulting decrement in VTA neuron firing rate. Because, however, nicotine causes dopamine release pharmacologically, independent of the smoker's actual experience, forebrain circuits, unavailable to conscious introspection, still receive a positive message that reinforces nicotine seeking and nicotine use. In short, addictive drugs, by virtue of their effects on dopamine, always signal "better than expected."

DRUG-INDUCED NEURAL PLASTICITY RELEVANT TO ADDICTION

In recent years, much neurobiologic research on addiction has focused on compulsive aspects of drug use, the ability of specific cues to activate drug seeking and craving, and the long persistence of stress and cue-dependent relapse risk. As described previously, compulsive drug use and the power of drug-associated cues reflect the usurpation of brain reward circuitry by drugs that directly cause dopamine release. The persistence of addiction reflects long-term changes in neurons, synapses, and circuits. Research over more than a decade has identified long-term changes in gene expression resulting from use of addictive drugs; recently, some long-lived alterations in gene expression have been attributed to drug-induced epigenetic mechanisms such as modification of chromatin.

Long-term changes in gene expression may render the addicted person susceptible to stress and may also create persistent changes in hedonic state and mood regulation that may motivate drug taking. By themselves, however, changes in gene expression do not explain the ability of exquisitely specific cues to activate drug seeking or, if seeking is impeded, intense subjective drug craving. The ability of specific cues to activate drug seeking and wanting is based on long-term associative memories consolidated under the influence of dopamine. Long-term memory formation represents perhaps the most persistent changes in brain function that may occur in adult life. The neural substrates of memory likely include alterations in synaptic weights, such as long-term potentiation (LTP) or long-term depression (LTD), and physical remodeling of dendritic spines.

The centrality of associative learning mechanisms for addiction was first recognized from clinical observation: much drug taking, and most notably late relapses, follows exposure to cues previously associated with drug use. Cues that can reinitiate drug use include environmental stimuli (e.g., persons with whom drugs have been used, drug paraphernalia) and bodily feelings. Because addictive drugs reliably increase synaptic dopamine as a result of their direct pharmacologic actions—indeed, they produce an excessive and grossly distorted dopamine signal—the brain receives a powerful impetus to connect the circumstances in which the drugs have been used with the motivation to take drugs again. Even if the drug is no longer pleasurable, the release of dopamine continues to reinforce drug wanting and seeking. Moreover, the reliability and quantity of dopamine release give drugs a marked advantage over natural rewards and other learned goals, including prosocial goals.

In the laboratory, it has been possible to study the effects of drug cues on neural circuits, physiology, and subjective responding in addicted human subjects. For example, drug-associated cues have been shown to elicit drug urges and physiologic responses (such as sympathetic activation), as well as activation of reward circuits in addicted human subjects. Using PET, cocaine-related cues have been shown to elicit dopamine release in the dorsal striatum in addicted subjects.

Investigations at the cellular and molecular levels have begun to identify the physiologic and molecular changes that underlie the effects of addictive drugs on reward-related memory processes. Among psychotropic drugs that have been examined, only those drugs that can cause addiction produce LTP in brain reward circuits including the VTA. Addictive drugs also activate transcription factors such as the cyclic adenosine monophosphate response element binding protein (CREB) and to alter the composition of activator protein 1 (AP-1) complexes in brain reward circuits. Dopamine and cocaine have been shown to regulate many genes downstream of CREB, AP-1, and other transcription factors. It has proved challenging, however, to determine which drug-regulated proteins are causally involved in addiction, as opposed to other processes such as physiologic dependence and withdrawal, or have no critical role at all. Part of the challenge is that while rodent models, including transgenic mouse models, have provided many insights into drug action and behavior, it is difficult to model human compulsion in animals, that is, to model a free-living and independent person who loses control over drug use while experiencing the negative consequences of that use. That said, a great body of detail is beginning to emerge about the neural processes that produce addiction.

NICOTINE AND TOBACCO

TONY P. GEORGE

DEFINITIONS

Cigarette smoking is the most common method of tobacco use (>90%), although other forms, including pipe tobacco, cigars, and smokeless tobacco, are common as well. Nicotine is the active ingredient that functions to reinforce tobacco addiction in all forms of tobacco.

EPIDEMIOLOGY

Cigarette smoking is the most preventable cause of morbidity and mortality in the Western world. In the United States, approximately 20% of the population uses tobacco, compared with 47% in 1965. Since the release of the surgeon general's report in 1965, smoking prevalence has been substantially reduced, but this reduction appears to have slowed in recent years, likely because the remaining smokers are refractory to tobacco treatment. Approximately 450,000 people die each year in the United States as a result of smoking-attributable medical illnesses such as lung cancer, chronic obstructive

pulmonary disease, cardiovascular disease, and stroke; the economic and health care costs of tobacco use exceed $400 billion annually. The use of smokeless tobacco (e.g., chewing tobacco) has increased, contributing to higher rates of oral pathologies such as precancerous oral lesions and cancers of the mouth and nasopharynx. Moreover, the health risks of environmental tobacco smoke have become increasingly clear, prompting widespread tobacco bans in public settings.

Worldwide, it is estimated that approximately 1.1 billion people use tobacco on a regular basis, including approximately 65 million in the United States. Tobacco smoking is increasing rapidly throughout the developing world, and it is estimated that cigarette smoking will cause about 450 million deaths worldwide in the next 50 years. Smoking begins at a younger age in new smokers, the rates of smoking in women are increasing, and more smokers are of a lower socioeconomic status. Reducing smoking prevalence by 50% would prevent 20 million to 30 million premature deaths in the first quarter of this century and 150 million in the second quarter.

For most smokers, quitting is the single most important thing they can do to improve their health. A recent prospective cohort study in Norway suggests that even with sustained reductions (>50%) in daily smoking consumption, there is little if any reduction in cardiovascular disease and lung or other smoking-related cancer risk, further substantiating the merits of quitting versus only reducing smoking.

PATHOBIOLOGY

Nicotine is the primary reinforcer in tobacco smoke, but more than 4000 components contribute to the sensory (non-nicotinic) aspects of cigarette smoking. The primary site of action of nicotine is the $\alpha_4\beta_2$ nicotinic acetylcholine receptor, and the endogenous neurotransmitter acting on this receptor is acetylcholine. Nicotinic acetylcholine receptors in the central nervous system are pentameric ion channel complexes comprising two α and three β subunits; the eight α subunits are designated α_2 through α_9, and the three β subunits are designated β_2 through β_4. This produces considerable diversity in subunit combinations, which may explain in part the region-specific and functional selectivity of nicotine's effects in the central nervous system. Activation of nicotinic acetylcholine receptors leads to Na^+/Ca^{2+} ion channel fluxes and neuronal membrane depolarization. The receptors are located presynaptically on several neurotransmitter-secreting neuron types in the central nervous system, including mesolimbic dopaminergic (DA) neurons that project from the ventral tegmental area to the nucleus accumbens. Activation of the nicotinic acetylcholine receptors on mesolimbic DA neurons leads to dopamine secretion in the nucleus accumbens.

At low concentrations of nicotine, $\alpha_4\beta_2$ nicotinic acetylcholine receptor stimulation of afferent GABAergic projections onto mesoaccumbal DA neurons predominates, leading to reduced mesolimbic DA neuron firing and dopamine release. At higher nicotine concentrations, $\alpha_4\beta_2$ nicotinic acetylcholine receptors desensitize, and activation of α_7 nicotinic acetylcholine receptors on glutamatergic projections predominates, leading to increased mesolimbic DA neuron firing and release. Within milliseconds of activation by nicotine, nicotinic acetylcholine receptors desensitize; after overnight abstinence, they resensitize. This may explain why most smokers report that the first cigarette in the morning is the most satisfying. Interestingly, recent positron emission tomography neuroimaging studies have shown that two to three puffs on a cigarette saturate the nicotinic acetylcholine receptors in the brain reward system, suggesting that although binding to these central receptors is an important first step in the effects of nicotine, it does not fully explain continued smoking behaviors.

CLINICAL MANIFESTATIONS

Although there is a subset of cigarette smokers who do not smoke every day, most smokers are daily users and have some degree of physiologic dependence on nicotine. Smokers typically describe a "rush" and feelings of alertness, relaxation, and satisfaction when smoking, and it is well known that nicotine has both stimulating and anxiolytic effects, depending on the basal level of arousal. Airway stimulation is an important aspect of smoking behavior, and additives such as menthol enhance the experience by increasing the taste and reducing the harshness of smoked tobacco.

Interestingly, the positive effects of cigarette smoking (e.g., taste, satisfaction) appear to be mediated by non-nicotine components of tobacco such as tar. Besides positive reinforcement, withdrawal, and craving, there are several secondary effects of nicotine and tobacco use that may contribute to both the maintenance of smoking and smoking relapse, including mood modulation (e.g., reduction of negative affect), stress reduction, and weight control. In addition, conditioned cues can elicit the urge to smoke even after prolonged periods of abstinence. Specific effects might be particularly relevant to smokers wishing to lose weight and those with psychiatric disorders (mood modulation, cognitive enhancement, stress reduction). These secondary effects may present additional targets for pharmacologic intervention in certain subgroups of smokers (e.g., schizophrenic, depressed, or weight-concerned smokers).

DIAGNOSIS

Nicotine dependence is established clinically by historical documentation of daily smoking (typically 10 to 40 cigarettes/day) for several weeks, evidence of tolerance (e.g., lack of adverse effects of nicotine, such as nausea), and the presence of symptoms of nicotine withdrawal upon smoking cessation. These withdrawal symptoms, which peak within 12 to 24 hours of cessation, include dysphoria, anxiety, irritability, decreased heart rate, insomnia (waking in the middle of the night), increased appetite, and craving for cigarettes. In addition, most dependent smokers state that they smoke their first cigarette of the day within 5 minutes of awakening. Timeline follow-back procedures and smoking diaries have been used successfully to monitor smoking consumption over time. Scales such as the Fagerstrom Test for Nicotine Dependence allow an assessment of the level of nicotine dependence, with a score of 4 or greater (on a scale of 0 to 10) consistent with physiologic dependence. Nicotine craving and withdrawal can be reliably monitored with validated scales such as the Tiffany Questionnaire for Smoking Urges and the Minnesota Nicotine Withdrawal Scale. These scales have excellent test-retest reliability and internal consistency in smokers with schizophrenia when compared with nonpsychiatric control smokers, suggesting that they can be used in psychiatric populations.

TREATMENT Rx

Psychosocial Treatments

Behavioral therapies (Table 31-1) are based on the theory that learning processes operate in the development, maintenance, and cessation of smoking. Behavioral treatments for smoking can facilitate the motivation to quit, emphasize the social and contextual aspects of smoking, and enhance overall success at smoking cessation. In most reviews, 6-month quit rates with behavioral therapies are 20 to 25%, and behavioral therapy typically increases quit rates up to twofold over standard medical advice. The primary goals of behavioral therapies in the treatment of tobacco dependence are to provide smokers with the necessary skills to help them quit smoking and avoid smoking in high-risk situations.

Brief Interventions

Brief interventions can increase the rate of smoking cessation and are strongly endorsed in the latest Department of Health and Human Services Guidelines on Tobacco Dependence Treatment. It is recommended that physicians use the five As with all patients: ask patients if they smoke, advise patients to quit, assess patients' level of motivation to quit, assist with attempts to quit, and arrange follow-up contacts. Providing self-help material is a form of brief intervention used to increase the motivation to quit and impart smoking cessation skills. Several recent studies have documented that minimal behavioral interventions such as community support groups, telephone counseling, and computer-generated tailored self-help materials can augment smoking cessation rates in controlled settings.

Motivational Interventions

The goal of motivational interviewing interventions is to elicit change by addressing ambivalence, increasing the patient's intrinsic motivation for change, and creating an atmosphere of acceptance in which patients take responsibility for making change happen. Brief motivational interventions have been developed for smoking cessation, and there is some evidence of increased smoking cessation using such techniques.

Cognitive-Behavioral Therapies

In cognitive-behavioral therapy, patients learn to identify situations in which they are likely to smoke and then plan to cope with these situations using behavioral (e.g., substitution of behavior) and cognitive (e.g., challenging thoughts) techniques. Some degree of efficacy has been observed in smokers using both individual and group counseling formats.

Relapse-Prevention (Coping Skills) Therapies

A large number of smokers relapse within 6 months of quitting. Focusing on relapse-prevention skills, including recognizing high-risk situations and coping with lapses, can be included in initial smoking cessation treatment or after a quit attempt.

Pharmacologic Treatments

Three classes of smoking cessation pharmacotherapies—nicotine replacement therapies (NRTs), sustained-release bupropion, and varenicline (Table 31-2)—have been approved by the Food and Drug Administration (FDA). Other off-label and novel medications are also discussed in this section.

Nicotine Replacement Therapies

The goal of NRT is to alleviate tobacco withdrawal, which allows smokers to focus on habit and conditioning factors when attempting cessation. After smoking cessation, NRT is gradually reduced so that minimal withdrawal occurs. NRTs rely on systemic venous absorption and thus do not produce the rapid high levels of arterial nicotine achieved when cigarette smoke is inhaled. Thus, individuals are unlikely to become addicted to NRTs. NRTs should be discontinued if the person restarts smoking, although safety concerns regarding smoking while using a nicotine patch appear to be less serious than previously thought. All commercially available forms of NRT are effective and increase quit rates by approximately 1.5- to 2.5-fold compared with placebo.[1] The transdermal patch, gum, and lozenge are sold over the counter (OTC); the nasal spray and inhaler require a prescription.

TABLE 31-1 BEHAVIORAL TREATMENTS FOR TOBACCO DEPENDENCE

TREATMENT	MECHANISM OF ACTION	EFFECTIVENESS RATING*
Brief interventions	Increase motivation to quit and impart cessation skills (e.g., community support, telephone counseling)	2
Cognitive-behavioral and relapse-prevention therapies	Use behavioral strategies to manage triggers; use cognitive coping strategies to target maladaptive thoughts and prevent relapse	1
Motivational interviewing	Promote patient's self-motivational statements to gain greater awareness of the problems related to smoking and increase intention to stop smoking	2

*1 = strong evidence to support efficacy; 2= moderate evidence to support efficacy; 3= little evidence to support efficacy.

Nicotine Gum

Nicotine ingested orally is extensively metabolized on the first pass through the liver. Nicotine polacrilex gum avoids this problem through buccal absorption. Nicotine gum, which was approved as an OTC medication in the United States in 1996, contains 2 or 4 mg of nicotine that is released from a resin by chewing. Nicotine gum should be administered by scheduled dosing (e.g., 1 piece of 2-mg gum/hour). The original recommended duration of treatment was 3 months, but many experts believe longer treatment is more effective. Nicotine absorption peaks 30 minutes after beginning to chew the gum. Venous nicotine levels from 2- and 4-mg gum are about one third and two thirds, respectively, of the steady-state nicotine levels (i.e., between cigarettes) achieved with cigarette smoking. Nicotine delivered by cigarettes is absorbed directly into the pulmonary arterial circulation. Thus, arterial levels from smoking are 5 to 10 times higher than those from the 2- and 4-mg gums. Absorption of nicotine in the buccal mucosa is decreased by an acidic environment, so patients should not drink beverages (e.g., coffee, soda, juice) immediately before, during, or after nicotine gum use.

Several placebo-controlled trials established the safety and efficacy of nicotine gum for smoking cessation.[1] There appears to be some evidence to support the use of higher doses of nicotine gum (4-mg pieces) in more highly dependent cigarette smokers (≥25 cigarettes/day), which supports the idea of matching the nicotine gum dose to the smoker's dependence level. Side effects from nicotine gum are rare and include those of mechanical origin (e.g., difficulty chewing, sore jaw) or local pharmacologic origin (e.g., burning in mouth, throat irritation). Tolerance to most side effects develops over the first week, and education about proper use of the gum (e.g., not chewing too vigorously) decreases side effects.

Nicotine Lozenges

Lozenges that deliver nicotine (2- and 4-mg preparations) by buccal absorption were approved for OTC use in the United States in 2002. Lozenges offer additional nicotine replacement options for smokers and allow greater absorption of nicotine compared with nicotine gum. Mild throat and mouth irritation were reported in preliminary trials. Nicotine lozenges have shown their superiority to placebo lozenges, with a significant reduction in nicotine craving and withdrawal.[1] Furthermore, higher doses of lozenges may be more efficacious in more highly dependent smokers, suggesting that similar to nicotine gum, lozenge dose can be matched to dependence level. Interestingly, the combination of nicotine lozenge with nicotine patch may lead to the highest long-term quit rates compared with nicotine replacement monotherapies and bupropion.[2]

TABLE 31-2 PHARMACOLOGIC TREATMENTS FOR TOBACCO DEPENDENCE

TREATMENT	MECHANISM OF ACTION	EFFECTIVENESS RATING*
NICOTINE REPLACEMENT THERAPIES†		
Gum (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
TNP (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Lozenge (OTC)	Slow nicotine absorption gradually reduces nicotine craving and withdrawal	1
Vapor inhaler (prescription)	Fast nicotine absorption leads to stimulation of nicotinic acetylcholine receptors, which rapidly reduces nicotine craving and withdrawal	1
Nasal spray (prescription)	Fast nicotine absorption leads to stimulation of nicotinic acetylcholine receptors, which reduces craving and withdrawal	1
NON-NICOTINE PHARMACOTHERAPIES		
Bupropion SR†	Blocks re-uptake of dopamine and norepinephrine; high-affinity, noncompetitive nicotinic acetylcholine receptor antagonism reduces nicotine reinforcement, withdrawal, and craving	1
Varenicline†	Acts as partial agonist of $\alpha_4\beta_2$ nicotinic acetylcholine receptors	1
Nortriptyline	Blocks re-uptake of norepinephrine and serotonin; probably reduces withdrawal symptoms and comorbid depressive symptoms; side effects limit utility	1-2
Clonidine	α_2-Adrenoreceptor agonist reduces nicotine withdrawal symptoms	2
Mecamylamine	Noncompetitive, high-affinity nicotinic acetylcholine receptor antagonist combined with TNP reduces nicotine reinforcement, craving, and withdrawal	2
Naltrexone	Endogenous μ-opioid peptide receptor antagonist reduces nicotine craving and withdrawal in combination with TNP; may reduce alcohol use and obviate cessation-induced weight gain	3
Monoamine oxidase inhibitors	Increased monoamine levels can reduce nicotine reinforcement, withdrawal, and craving; might be helpful for smokers with comorbid mood disorders	2
Rimonabant	Endocannabinoid receptor (CB_1) antagonist; has shown efficacy in smoking cessation trials and may be particularly useful in weight-concerned smokers	2
Nicotine vaccine	Limited evidence of efficacy for smoking cessation in early human trials; may have utility in relapse prevention	2

*1 = strong evidence to support efficacy; 2 = moderate evidence to support efficacy; 3 = little evidence to support efficacy.
†Approved by the Food and Drug Administration.
OTC = over the counter; SR = sustained release; TNP = transdermal nicotine patch.

Transdermal Nicotine Patch

The four transdermal nicotine patch (TNP) formulations take advantage of the ready absorption of nicotine through the skin. Three of the patches are for 24-hour use, and one is for 16-hour use. Starting doses are 21 or 22 mg/24-hour patch and 15 mg/16-hour patch. Patches are applied daily each morning. Nicotine administered by the patches is absorbed slowly, so that on the first day, venous nicotine levels peak 6 to 10 hours after application of the patch. Thereafter, nicotine levels remain fairly steady, with a decline from peak to trough of 25 to 40% with 24-hour patches. Nicotine levels obtained with the use of patches are typically half those obtained by smoking. After 4 to 6 weeks on a high-dose patch (21 or 22 mg/24 hours or 15 mg/16 hours), smokers are tapered to a medium dose (14 mg/24 hours or 10 mg/16 hours) and then, after another 2 to 4 weeks, to the lowest dose (7 mg/24 hours or 5 mg/16 hours). Most studies suggest that abrupt cessation of the use of patches causes no significant withdrawal. The recommended treatment is usually 6 to 12 weeks, but a 24-week course may be up to 50% more effective than an 8-week course.[3]

The overall efficacy of the TNP for smoking cessation has been well documented.[1] The effects are independent of patch type, treatment duration, tapering procedures, and behavioral therapy format or intensity, although it should be noted that behavioral treatment enhances outcomes compared with TNP alone. Severe adverse events have not been associated with nicotine patches. The most common minor side effects are skin reactions (50%), insomnia and increased or vivid dreams (15% with 24-hour patches), and nausea (5 to 10%). Tolerance to these side effects usually develops within a week. Rotation of patch sites decreases skin irritation. Insomnia reported in the first week after smoking cessation appears to be due to nicotine withdrawal rather than the nicotine patch itself. A 24-hour patch can be removed before bedtime to determine whether the insomnia is due to the nicotine patch. Without treatment, insomnia usually abates after 4 to 7 days. There appears to be little risk of dependence associated with patch use; only 2% of patch users continue to use it for an extended period after a cessation trial.

Nicotine Nasal Spray

Nicotine nasal spray is a nicotine solution in a nasal spray bottle similar to those used for saline sprays. This NRT was approved for the treatment of nicotine dependence in the United States in 1996. Nasal spray delivers droplets that average about 1 mg nicotine per administration, and the patient administers the spray (10 mg/mL) to each nostril every 4 to 6 hours. This formulation produces a more rapid rise in nicotine levels than does nicotine gum; the nicotine levels produced by nicotine spray fall between those produced by nicotine gum and by cigarettes. Peak nicotine levels occur within 10 minutes, and venous nicotine levels are about two thirds of between-cigarette levels. Smokers can use the nasal spray as needed up to 30 times/day for 12 weeks.

Randomized, double-blind, placebo-controlled trials of nasal spray versus placebo spray have established the safety and efficacy of nasal spray for smoking cessation.[4] These trials employed treatment for 3 to 6 months, and nicotine nasal spray led to a doubling of quit rates during active use. Differences were reduced or absent with extended follow-up, suggesting the need to continue using this agent. However, such long-term studies have not been published. Major side effects from nicotine nasal spray are nasal and throat irritation, rhinitis, sneezing, coughing, and watering eyes. Nicotine nasal spray may have some risk of dependence; prolonged use occurs in about 10% of smokers using the nasal spray, so follow-up is recommended.

Nicotine Inhaler

Cartridges (plugs) of nicotine (containing about 1 mg of nicotine each) are placed inside hollow cigarette-like plastic rods. The cartridges produce a nicotine vapor when warm air is passed through them. Absorption from a nicotine inhaler is primarily buccal rather than respiratory. More recent versions of inhalers produce a more rapid rise in venous nicotine levels compared with nicotine gum but a less rapid rise compared with nicotine nasal spray, with nicotine blood levels of about one third that of between-cigarette levels. Smokers are instructed to puff continually on the inhaler (0.013 mg/puff) during the day, and the recommended dosing is 6 to 16 cartridges daily. The inhaler is used as needed for about 12 weeks. No serious medical side effects have been reported with nicotine inhalers. Fifty percent of subjects report throat irritation or coughing. Randomized, double-blind, placebo-controlled trials have demonstrated the superiority of the nicotine inhaler to placebo inhalers for smoking cessation.[5] Results revealed a two- to threefold increase in quit rates (17 to 26%) at trial end point compared with placebo inhalers, and smaller differences at follow-up periods of 1 year or longer. These data support the short-term efficacy of inhalers in cigarette smokers, but longer-term trials are needed. There is also some modest concern about the risk of abuse, based on long-term use of the product in less than 10% of smokers.

Sustained-Release Bupropion

Bupropion, a phenylaminoketone atypical antidepressant agent, in the sustained-release (SR) formulation (Zyban), is a non-nicotine first-line pharmacologic treatment for nicotine-dependent smokers who want to quit. The mechanism of action in the treatment of nicotine dependence likely involves dopamine and norepinephrine reuptake blockade, as well as antagonism of high-affinity nicotinic acetylcholine receptors. The exact mechanism by which bupropion exerts antismoking effects is unclear. The goals of bupropion therapy are smoking cessation, reduction of nicotine craving and withdrawal symptoms, and prevention of cessation-induced weight gain.

The target dose of this agent in nicotine-dependent patients is 300 mg daily (150 mg twice a day). It is typically started 7 days before the target quit date (TQD) at 150 mg daily, then increased to 150 mg twice a day after 3 to 4 days. Unlike NRTs, there is no absolute requirement that smokers completely cease smoking by the TQD, although many smokers report a significant reduction in the urge to smoke and cravings, which facilitates cessation at the TQD when drug levels reach steady-state plasma levels. Some smokers gradually reduce their cigarette smoking over several weeks before quitting completely.

A pivotal multicenter study established the efficacy and safety of bupropion SR for the treatment of nicotine dependence, which led to its FDA approval in 1998. In a 7-week double-blind, placebo-controlled multicenter trial, four doses of bupropion SR (0, 100, 150, and 300 mg/day in twice-a-day dosing), in combination with weekly individual cessation counseling, were prescribed to 615 cigarette smokers using at least 15 cigarettes/day. At 1-year follow-up, cessation rates were 12.4%, 19.6%, 22.9%, and 23.1%, respectively. Bupropion SR treatment dose-dependently reduced weight gain associated with smoking cessation and significantly reduced nicotine withdrawal symptoms at doses of 150 and 300 mg/day.

Subsequently, the efficacy of combined bupropion SR and TNP was studied in a double-blind, placebo-controlled, randomized multicenter trial. A total of 893 cigarette smokers, using at least 15 cigarettes/day, were randomized to one of four experimental groups: (1) placebo bupropion + placebo patch; (2) placebo bupropion + TNP; (3) bupropion (300 mg/day) + placebo patch; or (4) bupropion + TNP. Cessation rates at the 1-year follow-up assessment were 15.6%, 16.4%, 30.3%, and 35.5% respectively. The bupropion groups did significantly better than the placebo and TNP alone groups, but the combination of bupropion and TNP was not significantly better than bupropion alone. Weight suppression after cessation was most robust in the combination therapy group.

Finally, a randomized, controlled trial demonstrated the efficacy of bupropion SR in relapse prevention after smoking cessation.[6] In individuals who had quit smoking with 7 weeks of bupropion (300 mg/day) treatment, bupropion SR versus placebo for 12 months delayed smoking relapse and resulted in weight gain.

Common side effects reported with bupropion administration in cigarette smokers are headache, nausea and vomiting, dry mouth, insomnia, and activation, most of which occur during the first week of treatment. The main contraindication for the use of bupropion is a past history of seizures of any cause. The rates of de novo seizures are low with this agent (<0.5%) at doses of 300 mg/day or less, but they have been observed when daily dosing exceeds 450 mg/day.

Varenicline

Varenicline tartrate (Chantix in the United States; Champix in Europe and Canada), a partial $\alpha_4\beta_2$ nicotinic acetylcholine receptor agonist, was approved as a first-line smoking cessation agent in the United States in 2006 and in Canada and Europe in 2007. The initial phase II trials of varenicline established its safety and efficacy in comparison to placebo and suggested an optimal dose of 2 mg/day.[7] Two independent but identical 12-week phase III trials comparing varenicline (2 mg/day) to bupropion SR (300 mg/day) were then conducted.[8,9] The quit rates for both studies were similar for continuous abstinence over the last 4 weeks (weeks 9 to 12) of the study. For study 1, the quit rates were as follows: varenicline, 43.9%; bupropion SR, 29.8%; and placebo, 17.6%.[8] For study 2, they were varenicline, 44.0%; bupropion SR, 29.5%; and placebo, 17.7%.[9] Quit rates were significantly higher for participants taking varenicline compared with bupropion SR, and both drugs resulted in significantly higher quit rates than placebo. Continuous abstinence over the follow-up period (weeks 9 to 52) was lower, but participants taking varenicline continued to show a higher rate of abstinence than those taking bupropion and placebo. Varenicline is also more effective in smoking relapse prevention compared with placebo.[8]

Varenicline reduces tobacco cravings and smoking satisfaction and is generally well tolerated. The most common adverse events reported in the initial studies were nausea and insomnia. Since the drug's approval, however, concerns have arisen over treatment-emergent neuropsychiatric events, including agitation, suicidal and homicidal ideation, mania, and psychosis. Thus, close monitoring of smokers, especially those with a history of psychiatric illness, is strongly advised when prescribing this agent.

Off-Label Medications

Other medications (see Table 31-2) have demonstrated some efficacy for tobacco treatment but are not approved for this indication and should be considered second-line treatments.

Novel Medications on the Horizon: Cannabinoid Antagonists and Nicotine Vaccines

Two novel pharmacologic strategies not yet approved in the United States may offer some additional strategies for smoking cessation and smoking relapse prevention. The cannabinoid receptor (CB_1) antagonist rimonabant

demonstrated promising results in clinical trials in the United States and Europe; at the 20 mg/day dose, it doubled the chance of quitting compared with placebo. Most notably, it potently suppresses smoking cessation–related weight gain. Side effects, which include nausea, vomiting, and tremors, are dose dependent. Unfortunately, rimonabant was not approved for smoking cessation by the FDA and was recently withdrawn as a pharmacologic treatment for obesity by the European Medications Agency owing to safety concerns related to the emergence of clinical depression. Trials with other CB_1 antagonists are in progress.

Nicotine vaccines are being developed by a number of companies. They appear to be well tolerated and enhance smoking cessation rates. Higher abstinence rates are observed as a function of higher serum antibody titers. The nicotine vaccine also shows promise for the prevention of smoking initiation or relapse and will likely be tested for these indications. Side effects include soreness at the injection site and hypersensitivity reactions to vaccine components.

PREVENTION

Tobacco dependence remains one of the leading preventable causes of morbidity and mortality in the Western world. Although smoking cessation therapies are among the most cost-effective and proven therapies in medicine, most health care providers do not identify tobacco use in their patients. The U.S. Public Health Service recently published updated clinical practice guidelines for nicotine dependence that provide standards for the treatment of tobacco dependence. In addition, effective tobacco policies such as state taxes and prevention efforts targeted at reducing the initiation of tobacco use by youths and adults are critical elements in the overall strategy to reduce the burden of tobacco-related disease and related social and health care costs.

PROGNOSIS

The prognosis for tobacco smokers who quit is excellent in terms of years of life and quality of life gained. Bans on smoking in public places can reduce local rates of acute myocardial infarction by about 17%.

Although medications and behavioral treatments have documented efficacy in treating tobacco dependence, these therapies must be used in combination to achieve the best overall results and ensure adequate skill acquisition and treatment adherence. Novel treatment and prevention interventions, such as the nicotine vaccine and the employment of personalized medicine—matching the right medications to smokers with preferential responses using pharmacogenetic approaches—are generating considerable excitement in the tobacco treatment field and may be available within the next decade. Further, given the high rates of tobacco use and dependence in psychiatric populations and the lower rates of quitting in this subset of smokers compared with the general population, the specific adaptation of tobacco treatments to mentally ill smokers will be of paramount importance in improving prognosis and outcome in these hard-to-treat smokers. Additional future challenges include developing safer and more effective smoking cessation therapies and making these therapies available to all smokers who wish to quit.

ALCOHOL ABUSE AND DEPENDENCE

PATRICK G. O'CONNOR

DEFINITION

A variety of terms have been used to describe the spectrum of medical, psychological, behavioral, and social problems associated with excessive consumption of alcohol (*alcohol problems*). *Alcoholism* is perhaps the most widely used term to describe patients with alcohol problems. In an attempt to define *alcoholism* more precisely, a panel of 23 experts convened by the National Council on Alcoholism and Drug Dependence and the American Society of Addiction Medicine developed a definition of alcoholism that included "a primary chronic disease with genetic, psychosocial and environmental factors . . . often progressive and fatal . . . characterized by impaired control over drinking, preoccupation with the drug alcohol, use of alcohol despite future consequences, and distortions of thinking, most notably denial." Because the term *alcoholism* is so broad, it also can be imprecise in defining the entire spectrum of alcohol problems.

Abstainers are individuals who consume no alcohol. *Moderate drinking* is defined by the National Institute on Alcohol Abuse and Alcoholism as the average number of drinks consumed daily that places an adult at low risk for alcohol problems. There is some epidemiologic evidence to suggest that moderate drinking may have some health benefits by reducing the risk of cardiovascular disease (Chapter 51). The scope of alcohol consumption that imparts this benefit may be low, however (e.g., less than one drink per day).

At-risk drinking is a level of alcohol consumption that imparts health risks (Table 32-1). This category of drinking behavior has been identified on the

TABLE 32-1 TERMS AND CRITERIA FOR PATTERNS OF ALCOHOL USE

AT-RISK DRINKING
Men: >14/week or >4 drinks/day Women: >7/week or >3 drinks/day
ALCOHOL ABUSE
Maladaptive pattern of alcohol use leading to clinically significant impairment or distress, manifested within a 12-month period by one or more of the following: Failure to fulfill role obligations at work, school, or home Recurrent use in hazardous situations Legal problems related to alcohol Continued use despite alcohol-related social or interpersonal problems Symptoms have never met criteria for alcohol dependence
ALCOHOL DEPENDENCE
Maladaptive pattern of alcohol use leading to clinically significant impairment or distress, manifested within a 12-month period by three or more of the following: Tolerance (either increasing amounts used or diminished effects with the same amount) Withdrawal (withdrawal symptoms or use to relieve or avoid symptoms) Use of larger amounts for a longer period than intended Persistent desire or unsuccessful attempts to cut down or control use Great deal of time spent obtaining, using, or recovering from use Important social relationships, occupations, or recreational activities given up or reduced Use despite knowledge of alcohol-related physical or psychological problems

basis of epidemiologic evidence that certain threshold levels of alcohol consumption are associated with increased risk of specific health problems. At-risk drinking is defined differently for men younger than 65 years than for women of all ages because of generally lower body weights and lower rates of metabolism of alcohol in women; the definition in men older than 65 years is the same as in women because of the age-related increased risk of alcohol problems, in part due to changes in alcohol metabolism in older individuals. *Binge drinking* or *heavy drinking* is the episodic consumption of large amounts of alcohol, usually five or more drinks per occasion for men and four or more drinks per occasion for women. One standard drink contains 12 g of pure alcohol, an amount equivalent to that contained in 5 ounces of wine, 12 ounces of beer, or 1.5 ounces of 80-proof spirits. *Problem drinking* refers to a level of alcohol consumption that causes any problems for the patient (medical, psychiatric, behavioral, or social—*alcohol problems*).

Alcohol abuse and *alcohol dependence,* which are alcohol use disorders defined in the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition, require the presence of specific social or clinical phenomena (see Table 32-1). *Alcohol abuse* includes criteria that indicate social dysfunction or use in high-risk situations (e.g., driving). *Alcohol dependence* includes social consequences along with criteria related to physiologic aspects of dependence (e.g., tolerance, loss of control) and use despite physical or psychological problems. The distinction between *alcohol abuse* and *alcohol dependence* is important given the general need for more intensive treatment services for patients who are alcohol dependent.

EPIDEMIOLOGY

In national surveys, 64% of American adults reported that they use alcoholic beverages (liquor, wine, or beer), whereas 36% reported that they were abstinent. Among individuals who use alcohol, many experience problems because of their drinking. It has been estimated that more than $100 billion is spent by American society each year to treat alcohol use disorders and to recover the costs of alcohol-related economic losses. Excessive alcohol consumption ranks as the third leading preventable cause of death in the United States after cigarette smoking and obesity. More than 100,000 deaths per year in the United States are attributed to alcohol use disorders.

Population-based epidemiologic studies have shown that alcohol use disorders are among the most prevalent medical, behavioral, or psychiatric disorders in the general population. An epidemiologic survey of the general population in the United States documented a prevalence of alcohol abuse and dependence estimated to be between 7.4 and 9.7%. The lifetime prevalence of abuse and dependence is estimated to be even higher. Despite higher thresholds and tolerance, men are at least twice as likely as women to meet criteria for alcohol abuse and dependence by standard diagnostic survey techniques. Although sociodemographic features, such as young age, low income, and low education level, have been associated with an increased risk for problem drinking, alcohol use disorders are prevalent throughout all sociodemographic groups, and all individuals should be screened carefully. The "skid row" stereotype of the alcohol-dependent patient is much more the exception than the rule.

The prevalence of alcohol use disorders is higher in most health care settings than it is in the general population because alcohol problems often result in treatment-seeking behaviors. The prevalence of problem drinking in general outpatient and inpatient medical settings has been estimated between 15 and 40%. These data strongly support the need for physicians to screen all patients for alcohol use disorders.

PATHOBIOLOGY

Beverage alcohol contains ethanol, which acts as a sedative-hypnotic drug. Alcohol is absorbed rapidly into the blood stream from the stomach and intestinal tract. Because women have lower levels of gastric alcohol dehydrogenase, the enzyme primarily responsible for metabolizing alcohol, they experience higher blood alcohol concentrations than do men who consume similar amounts of ethanol per kilogram of body weight. The absorption of alcohol can be affected by other factors, including the presence of food in the stomach and the rate of alcohol consumption. By means of metabolism in the liver, alcohol is converted to acetaldehyde and acetate (Fig. 32-1). Metabolism is proportional to an individual's body weight, but a variety of other factors can affect how alcohol is metabolized. A genetic variation in a significant proportion of the Asian population alters the structure of an aldehyde hydrogenase isoenzyme, resulting in the development of an alcohol flush reaction, which includes facial flushing, hot sensations, tachycardia, and hypotension.

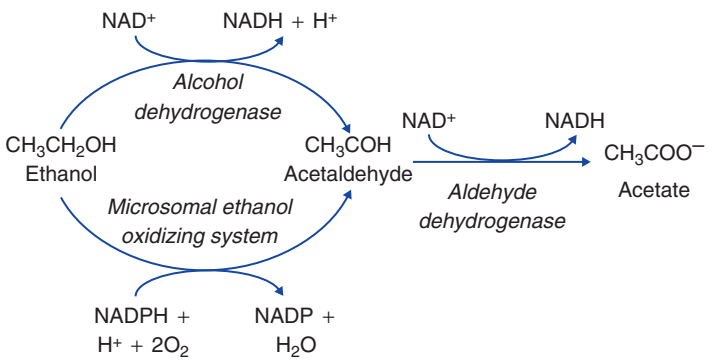

FIGURE 32-1. Ethanol metabolism. Alcohol dehydrogenase predominates at low to moderate ethanol doses. The microsomal ethanol-oxidizing system is induced at high ethanol levels of chronic exposure and by certain drugs. Aldehyde dehydrogenase inhibition (genetic or drug induced) leads to acetaldehyde accumulation.

In the brain, alcohol seems to affect a variety of receptors, including γ-aminobutyric acid (GABA), *N*-methyl-D-aspartate, and opioid receptors. Glycinuric and serotoninergic receptors also are thought to be involved in the interaction between alcohol and the brain. The phenomena of reinforcement and cellular adaptation are thought, at least in part, to influence alcohol-dependent behaviors. Alcohol is known to be reinforcing because withdrawal from ethanol and ingestion of ethanol itself are known to promote further alcohol consumption. After chronic exposure to alcohol, some brain neurons seem to adapt to this exposure by adjusting their response to normal stimuli. This adaptation is thought to be responsible for the phenomenon of tolerance, whereby increasing amounts of alcohol are needed over time to achieve desired effects. Although much has been learned about the variety of effects alcohol can have on various brain receptors, no single receptor site has been identified. A variety of neuropsychological disorders are seen in association with chronic ethanol use, including impaired short-term memory, cognitive dysfunction, and perceptual difficulties.

Although the brain is the primary target of alcohol's actions, a variety of other tissues have a major role in how alcohol affects the human body. Direct liver toxicity may be among the most important consequences of acute and chronic alcohol use (Chapter 155). A variety of histologic abnormalities ranging from inflammation to scarring and cirrhosis have been described. The pathophysiologic mechanism of these effects is thought to include the direct release of toxins and the formation of free radicals, which can interact negatively with liver proteins, lipids, and DNA. Alcohol also has substantial negative effects on the heart and cardiovascular system. Direct toxicity to myocardial cells frequently results in heart failure (Chapter 58), and chronic heavy alcohol consumption is considered to be a major contributor to hypertension (Chapter 67). Other organ systems that experience significant direct toxicity from alcohol include the gastrointestinal tract (esophagus, stomach), immune system (bone marrow, immune cell function), and endocrine system (pancreas, gonads).

CLINICAL MANIFESTATIONS

Alcohol has a variety of specific acute and chronic effects. The acute effects seen most commonly are alcohol intoxication and alcohol withdrawal. Chronic clinical effects of alcohol include almost every organ system.

Acute Effects

Alcohol Intoxication

After entering the blood stream, alcohol rapidly passes through the blood-brain barrier. The clinical manifestations of alcohol intoxication are related directly to the blood level of alcohol. Because of tolerance, individuals chronically exposed to alcohol generally experience less severe effects at a given blood alcohol level than do individuals who are not chronically exposed to alcohol.

The symptoms of mild alcohol intoxication in nontolerant individuals typically occur at blood alcohol levels of 20 to 100 mg/dL and include euphoria, mild muscle incoordination, and mild cognitive impairment. At higher blood alcohol levels (100 to 200 mg/dL), more substantial neurologic dysfunction occurs, including more severe mental impairment, ataxia, and prolonged reaction time. Individuals with blood alcohol levels in these ranges can be obviously intoxicated with slurred speech and lack of coordination.

These effects progress as the blood alcohol level rises to higher levels, to the point at which stupor, coma, and death can occur at levels equal to or greater than 300 to 400 mg/dL, especially in individuals who are nontolerant to the effects of alcohol. The usual cause of death in individuals with very high blood levels of alcohol is respiratory depression and hypotension.

Alcohol Withdrawal Syndrome

Alcohol withdrawal can occur when individuals decrease their alcohol use or stop using alcohol altogether. The severity of symptoms can vary greatly. Many individuals experience alcohol withdrawal without seeking medical attention, whereas others require hospitalization for severe illness. Because ethanol is a central nervous system depressant, the body's natural response to withdrawal of the substance is a hyperexcitable neurologic state. This state is thought to be the result of adaptive neurologic mechanisms being unrestrained by alcohol, with an ensuing release of a variety of neurohumoral substances, including norepinephrine. In addition, chronic exposure to alcohol results in a decrease in the number of GABA receptors and impairs their function.

The clinical manifestations of alcohol withdrawal include hyperactivity resulting in tachycardia and diaphoresis. Patients also experience tremulousness, anxiety, and insomnia. More severe alcohol withdrawal can result in nausea and vomiting, which can exacerbate metabolic disturbances. Perceptual abnormalities, including visual and auditory hallucinations and psychomotor agitation, are common manifestations of more moderate to severe alcohol withdrawal. Grand mal seizures commonly occur during alcohol withdrawal, although they do not generally require treatment beyond the acute withdrawal phase.

The time course of the alcohol withdrawal syndrome can vary within an individual and by symptom complex, and the overall duration of symptoms can be a few to several days (Fig. 32-2). Tremor is typically among the earliest symptoms and can occur within 8 hours of the last drink. Symptoms of tremulousness and motor hyperactivity typically peak within 24 to 48 hours. Although mild tremor typically involves the hands, more severe tremors can involve the entire body and greatly impair a variety of basic motor functions. Perceptual abnormalities typically begin within 24 to 36 hours after the last drink and resolve within a few days. When withdrawal seizures occur, they are typically generalized tonic-clonic seizures and most often occur within 12 to 24 hours after reduction of alcohol intake. Seizures can occur, however, at later time periods as well.

The most severe manifestation of the alcohol withdrawal syndrome is delirium tremens. This symptom complex includes disorientation, confusion, hallucination, diaphoresis, fever, and tachycardia. Delirium tremens typically begins after 2 to 4 days of abstinence, and the most severe form can result in death.

Chronic Effects

Acute manifestations, including intoxication and withdrawal, are generally stereotypical in their appearance and time course, but chronic manifestations tend to be more varied. Many patients with alcohol dependence may be without evidence of any chronic medical manifestations for many years. As time goes on, however, the likelihood that one or more of these manifestations will occur increases considerably. All major organ systems can be affected, but the primary organ systems involved are the nervous system, cardiovascular system, liver, gastrointestinal system, pancreas, hematopoietic system, and endocrine system (Table 32-2). Patients who drink are at risk for a variety of malignant neoplasms, such as head and neck, esophageal, and liver cancers (Chapters 196, 198, and 202). Excessive alcohol use often causes significant psychiatric and social morbidity that can be more common and more severe than the direct medical effects, especially earlier in the course of problem drinking.

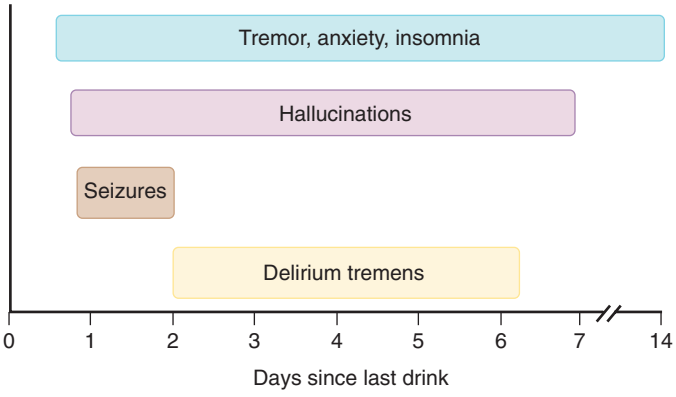

FIGURE 32-2. Time course of alcohol withdrawal.

Nervous System

In addition to the acute neurologic manifestations of intoxication and withdrawal, alcohol has major chronic neurologic effects. About 10 million Americans have identifiable nervous system impairment from chronic alcohol use. Individual predisposition to these disorders is highly variable and is related to genetics, environment, sociodemographic features, and gender; the relative contribution of these factors is unclear.

In the central nervous system, the major effect is cognitive impairment. Patients may present with mild to moderate short-term or long-term memory problems or may have severe dementia resembling Alzheimer's disease (Chapter 409). The degree to which the direct toxic effect of alcohol is responsible for these problems or the impact of alcohol-related nutritional deficiencies is uncertain (Chapter 425). The deficiency of vitamins such as thiamine may play a major role in promoting alcoholic dementia and severe cognitive dysfunction, as is seen in Korsakoff's syndrome. Alcohol also causes a polyneuropathy that can present with paresthesias, numbness, weakness, and chronic pain (Chapters 425 and 428). As with the central nervous system, peripheral nervous system effects are thought to be caused by a combination of the direct toxicity of alcohol and nutritional deficiencies. A small proportion (<1%) of patients with alcohol dependence may develop midline cerebellar degeneration, which presents as an unsteady gait.

Cardiovascular System

The most common cardiovascular complications of chronic alcohol consumption are cardiomyopathy, hypertension, and supraventricular arrhythmias. Alcoholic cardiomyopathy can present clinically in a manner similar to

TABLE 32-2 ALCOHOL-RELATED COMPLICATIONS

SYSTEM/REALM OF PROBLEM	COMPLICATIONS
Nervous system	Intoxication Withdrawal Cognitive impairment Cerebellar degeneration Peripheral neuropathy
Cardiovascular system	Cardiac arrhythmias Chronic cardiomyopathy Hypertension
Liver	Fatty liver Alcoholic hepatitis Cirrhosis
Gastrointestinal tract	
Esophagus	Chronic inflammation Malignant neoplasms Mallory-Weiss tears Esophageal varices
Stomach	Gastritis Peptic ulcer disease
Pancreas	Acute pancreatitis Chronic pancreatitis
Other medical problems	Cancers: mouth, oropharynx, esophagus Hepatoma Pneumonia Tuberculosis
Psychiatric	Depression Anxiety Suicide
Behavioral and psychosocial	Injuries Violence Crime Child or partner abuse Tobacco, other drug abuse Unemployment Legal problems

other causes of heart failure (Chapter 58). It is the most common cause of nonischemic cardiomyopathy in Western countries, accounting for about 45% of cases. Like these other causes, alcoholic cardiomyopathy also responds to conventional treatments of heart failure (Chapter 59). Abstinence from alcohol can result in significant improvement in cardiomyopathy in some patients. Increasing levels of alcohol consumption also are associated with increasing levels of systolic and diastolic hypertension (Chapter 67).

The most common arrhythmias associated with chronic alcohol use include atrial fibrillation and supraventricular tachycardia; these are seen commonly in the setting of acute intoxication and withdrawal (Chapter 64). The prevalence of alcohol-induced arrhythmias is unclear. Alcoholic cardiomyopathy also is associated with arrhythmias, in particular, ventricular arrhythmias (Chapter 65).

Liver

Alcohol abuse is the major cause of morbidity and mortality from liver disease in the United States. It has been estimated that there are more than 2 million people with known alcoholic liver disease in the United States. Factors that predispose to early liver disease include the quantity and duration of alcohol exposure, female gender, and malnutrition. The range of clinical manifestations includes acute fatty liver, alcoholic hepatitis, and cirrhosis (Chapter 156). Fatty liver associated with alcohol ingestion can be asymptomatic or associated with nonspecific abdominal discomfort; it generally improves with abstinence from alcohol. Alcoholic hepatitis can present as an asymptomatic condition identified through abnormalities in liver enzymes or as an acute episode with abdominal pain, nausea, vomiting, and fever. Patients with alcoholic hepatitis have particularly high levels of aspartate aminotransferase in the blood and elevated levels of γ-glutamyltransferase. Alcoholic hepatitis typically improves with abstinence from alcohol.

Alcohol-related cirrhosis is a major cause of death in the United States (Chapter 157). Although patients are often asymptomatic, patients with more advanced cirrhosis may present with a variety of symptoms and signs, including jaundice, ascites, and coagulopathy. Cirrhosis also is associated with gastrointestinal bleeding from esophageal varices (Chapter 140). Although there is some controversy about the use of liver transplantation to treat patients with alcoholic cirrhosis, many believe that patients in established recovery are good candidates for liver transplantation (Chapter 157).

Gastrointestinal Disease

Chronic alcohol use is associated with a variety of esophageal problems, including esophageal varices, Mallory-Weiss tears, and squamous cell carcinoma of the esophagus. The risk of squamous cell carcinoma is increased further in patients who smoke tobacco and drink alcohol. Patients with these problems can present with difficulty swallowing, chest pain, gastrointestinal blood loss, and weight loss. Acute alcoholic gastritis typically presents with abdominal discomfort, nausea, and vomiting (Chapter 137).

Pancreas

The risk of pancreatitis in individuals with alcohol dependence is approximately four times that in the general population. Quantity and duration of alcohol exposure and a history of pancreatitis are predictive of future episodes. Acute alcoholic pancreatitis, which may present with severe abdominal pain, nausea, vomiting, fever, and hypotension, can be life-threatening (Chapter 146). Individuals who have recurrent acute pancreatitis may develop chronic pancreatitis, which typically presents with chronic abdominal pain, malabsorption, weight loss, and malnutrition.

Hematopoietic System

The anemia that commonly is seen in patients with chronic alcohol problems can be multifactorial (e.g., blood loss, nutrient deficiency, secondary to liver disease and hypersplenism). Studies of selected inpatients with alcohol dependence showed the prevalence of anemia to range from about 10 to 60%. Gastrointestinal blood loss due to Mallory-Weiss tears (Chapter 137), alcoholic gastritis (Chapter 134), or esophageal varices (Chapters 137 and 156) may be a key factor, and many patients develop subsequent iron deficiency. Dietary folate deficiency can be associated with megaloblastic anemias (Chapter 167). Alcohol also has a direct toxic effect on the bone marrow, which can lead to sideroblastic anemia that resolves after abstinence. Alcohol can suppress megakaryocyte production and cause thrombocytopenia, which may manifest as petechiae or bleeding (Chapter 175); the thrombocytopenia is particularly sensitive to abstinence, with platelet counts usually rebounding or returning to normal within 5 to 7 days after cessation of alcohol intake. Alcohol also appears to interfere directly with platelet function. Alcohol-related immune dysfunction, as evidenced by decreased production and function of white blood cells and derangement in humoral and cell-mediated immunity, partly explains why alcohol-dependent individuals are at higher risk for infectious diseases, such as pneumonia and tuberculosis.

Malignant Neoplasms

Alcohol intake has been associated with upper digestive, respiratory, and liver malignant neoplasms. Alcohol use is associated with squamous cell carcinomas of the esophagus (Chapter 198) and of the head and neck (Chapter 196). The co-occurrence of alcohol and tobacco abuse seems to be synergistic. Either heavy alcohol use or smoking individually increases the rate of oropharyngeal cancer by about six or seven times that of the general population, whereas the rate for people with both risk factors is about 40 times that of the general population. Patients with alcohol-induced liver disease who also have a history of hepatitis B or C are at particularly increased risk for hepatocellular carcinoma (Chapter 202).

Chronic alcohol use also has been associated with malignant neoplasms of the breast (Chapter 204), prostate (Chapter 207), pancreas (Chapter 200), cervix (Chapter 205), lung (Chapter 197), and colon (Chapter 199). Women who have more than one or two alcoholic drinks per day may increase their breast cancer risk 1.5-fold or more. Hormonal mechanisms and direct carcinogenic effects of alcohol have been postulated as causes of this association. The association of cervical cancer with alcohol dependence may be due to alcohol-associated high-risk sexual behaviors that are thought to increase the risk of cervical cancer.

Other Medical Issues

Gout has been associated with alcohol abuse, and flares can occur at lower serum urate levels than in nonalcoholic patients (Chapter 281). Alcoholic ketoacidosis (Chapter 120), which usually follows an alcoholic binge, presents as nausea, vomiting, abdominal pain, and volume depletion. Typically, ketoacidosis is seen with low or normal glucose readings. Mild or nonspecific abnormalities in thyroid function, especially in patients with underlying liver disease, may reflect abnormalities in the clearance of thyroid-stimulating hormone or the impact of elevated circulating estrogens. Infertility and menstrual irregularities have been associated with chronic alcohol consumption, presumably due to alcohol-induced hypothalamic-pituitary dysfunction, gonadal toxicity, and impaired hepatic metabolism of circulating hormones. Hypogonadism is highly prevalent in male alcoholics with cirrhosis. Alcohol dependence also is associated with higher rates of dental and periodontal disease (Chapter 433) and with a variety of dermatologic problems, including spider angiomas and, in patients with poor hygiene, skin infestations. Both at-risk drinking and alcohol dependence have been shown to be associated with an increased risk of hospital-acquired infections, sepsis, and mortality, especially in intensive care patients.

Psychiatric Issues

Psychiatric symptoms and illnesses are exceedingly common among individuals with alcohol problems. The prevalence of anxiety disorders is about 40%, and the prevalence of affective disorders is about 30%. Antisocial personality disorder is also more common in individuals with alcohol problems than in the general population. These psychiatric problems are more prevalent during periods of heavy drinking and withdrawal. All patients with alcohol use disorders require careful screening for psychiatric illnesses. Effective treatment of underlying psychiatric disorders may result in improved drinking behaviors.

Other Behavioral and Psychosocial Issues

Alcohol commonly is the underlying cause of domestic abuse, injuries, trauma, motor vehicle crashes, and burns. Patients presenting with injuries should be questioned carefully about their alcohol use. Tobacco (Chapter 31) and other drug abuse (Chapter 33) is more prevalent in people with alcohol problems than in the general population.

DIAGNOSIS

Data from the history, physical examination, and laboratory generally are needed to provide a complete picture of the extent of alcohol problems in affected patients (Table 32-3).

TABLE 32-3 DIAGNOSIS OF ALCOHOL PROBLEMS

HISTORY

Step 1: Ask all patients about current and past use.
- Do you drink alcohol (ever or currently)?
- Do you have a family history of alcohol problems?

Step 2: Obtain detailed history regarding quantity and frequency of alcohol use.
- What types of alcohol do you consume?
- How often do you drink?
- How much do you usually drink?
- Do you ever drink more, and if so, how much?

Step 3: Standardized questionnaire
- CAGE questions:
- Have you ever felt that you should ***c***ut down on your drinking?
- Have people ***a***nnoyed you by criticizing your drinking?
- Have you ever felt bad or ***g***uilty about drinking?
- Have you ever taken a drink first thing in the morning (***e***ye opener) to steady your nerves or get rid of a hangover?

Step 4: Assess specific areas in suspected or known problem drinkers.
- Criteria for alcohol abuse and dependence
- Evidence of medical and psychiatric problems
- Evidence of behavioral or social problems
- Use of other substances
  - Tobacco
  - Mood-altering prescription drugs
  - Illicit drugs (e.g., heroin, cocaine)
- Prior alcohol or substance abuse treatment

PHYSICAL EXAMINATION

Thorough and complete examination important in all patients
Focus attention to system with identified problems
In all patients, carefully examine
- Central and peripheral nervous systems
- Cardiovascular system
- Liver
- Gastrointestinal tract

LABORATORY STUDIES (IN SELECTED PATIENTS)

Liver enzymes
Coagulation studies
Complete blood count
Carbohydrate-deficient transferrin

Discussing the Diagnosis with Patients

In discussing alcohol problems, it is crucial that physicians be sensitive to the stigma and shame that may be felt by patients with alcohol problems and by their families. Alcohol-related diagnoses or problems should be discussed in a nonjudgmental manner, which forges a partnership and indicates commitment to helping with whatever problems the patients might have. Setting the stage for the discussion should include educating patients about the various levels of alcohol problems (e.g., at-risk drinking, alcohol abuse, alcohol dependence) so that patients have an understanding of the spectrum of alcohol problems. Many patients may have a skewed view of what qualifies as problem drinking and may believe that only individuals with severe alcohol problems are truly problem drinkers. The history, physical examination, and laboratory studies should be provided as "proof" that a problem may or does exist.

History

A four-step approach to the alcohol history includes comprehensive questions about alcohol use and a thorough evaluation for alcohol-related problems.

Step 1: Ask All Patients about Current and Past Alcohol Use

A single question—Do you currently or have you ever used alcohol?—can identify quickly patients who are not lifetime abstainers and require further screening. Patients who answer yes to this question should proceed through the subsequent three steps. Patients who answer no can be classified as lifetime abstainers from alcohol and require no further questioning unless their answer changes over time. It is crucial to ask about current and past alcohol use because many patients who meet lifetime criteria for alcohol dependence but who are currently in recovery answer no to the question about current use; unless it is specifically asked about, important past use information may be missed.

Step 2: Obtain Detailed History Regarding Quantity and Frequency of Alcohol Use

A question to be asked routinely is, What type or types of alcoholic drinks (beer, wine, spirits) do you consume? Many patients do not consider the use of beer or wine "drinking." Quantity should be determined for typical use—How much do you usually drink on a typical drinking day?—and for range of use—Do you ever drink more than your usual amount, and if so, how much? This second question can be particularly important for identifying binge drinking. Quantity questions offer easy identification of at-risk drinking. Asking about the frequency of alcohol consumption—How often do you drink?—helps distinguish daily from nondaily alcohol users. Binge drinkers who drink only on weekends tend to have significant alcohol problems yet not be daily drinkers. A major goal of step 2 is to acquire a complete characterization of current alcohol use behaviors and the pattern of quantity and frequency of alcohol use during the patient's lifetime.

Step 3: Use Standardized Screening Instruments

Many standardized questionnaires have been developed to detect alcohol abuse and dependence. The two questionnaires that have been evaluated most extensively in medical settings are the CAGE (Cut down, Annoyed, Guilty, and Eye opener) questionnaire (see Table 32-3) and the Alcohol Use Disorder Identification Test (AUDIT). The CAGE questionnaire includes four questions and is scored by giving 1 point for each positive response. Given that the word *ever* is used in the CAGE questions, by definition this instrument is designed to detect lifetime alcohol problems and does not distinguish between lifetime problems and current problems. To screen for alcohol abuse and dependence, the CAGE has a sensitivity of 43 to 94% and a specificity of 70 to 97% when a cutoff score of 2 is used to indicate a "positive" result.

The AUDIT's ten questions cover the quantity and frequency of alcohol use, drinking behaviors, adverse psychological symptoms, and alcohol-related problems. It was developed by the World Health Organization to identify hazardous (e.g., at-risk) drinking and harmful (e.g., alcohol use that results in physical or psychological harm) drinking. In contrast to the CAGE questionnaire, the AUDIT focuses on recent (current to past year) drinking behaviors. Each question is scored 0 to 4 (range for total score is 0 to 40), and a total score of 8 is considered to be a positive result.

Step 4: Assess Specific Areas in Suspected or Known Problem Drinkers

Questions asked in step 4 are based on the results of the questions asked in steps 2 and 3 to obtain more detailed information in patients with potential alcohol problems. Even patients who do not screen positive on the CAGE questionnaire may warrant detailed questioning about alcohol abuse and dependence (see Table 32-1), especially if they are drinking at or above at-risk levels or there is other evidence of possible alcohol problems. A detailed review for evidence of alcohol-related medical and psychiatric problems should occur, and the need for further medical and psychiatric evaluation should be determined. The physician should look for evidence of behavioral and social problems commonly associated with alcohol use and screen for family and occupational dysfunction and other problems, such as domestic violence. Patients should be asked about their use of tobacco, mood-altering prescription medications, and illicit drugs such as heroine and cocaine.

Finally, many patients with alcohol problems have prior treatment episodes that should be detailed. The inquiry should include questions not only about formal alcohol treatment (including number of episodes, duration of treatment, and inpatient versus outpatient treatment) but also about more informal treatments, such as attendance at self-help groups like Alcoholics Anonymous (AA). For patients who require a referral for treatment, knowledge of prior treatment experience is a crucial determinant of future referral recommendations.

The National Institute on Alcohol Abuse and Alcoholism has published *Helping Patients Who Drink Too Much: A Clinician's Guide,* which provides a similar approach to screening and evaluating patients for alcohol-related problems and includes an appendix of useful supporting materials.

Physical Examination

Patients with potential alcohol use disorders require a detailed physical examination to complement the history. In addition, attention should be focused on detecting common alcohol-related problems, including the nervous system, cardiovascular system, liver, and gastrointestinal system (see Table 32-2).

Laboratory Findings

A variety of laboratory tests have been proposed to aid screening for alcoholic abuse and dependence. Aminotransferase levels, red blood cells, mean corpuscular volume, and carbohydrate-deficient transferrin, alone or in combination, are not as effective as screening questionnaires, such as the CAGE and the AUDIT.

Laboratory tests do have a role in diagnosis and assessment of patients with potential alcohol problems. Routine laboratory testing including liver enzymes (Chapter 149), bilirubin, complete blood count, and prothrombin time should be obtained in all patients with alcohol problems on a regular basis so that an appropriate and complete picture of the effects of alcohol on the individual can be obtained.

PROGNOSIS

Alcohol abuse and dependence are chronic disorders that are characterized by exacerbations and remissions. The prognosis is better for patients who seek treatment and receive it in a systematic way (Table 32-6), but it can be poor for patients with advanced liver disease and continued alcohol use. In addition, the use of combinations of medications (e.g., naltrexone plus acamprosate) is under investigation.

PREVENTION AND TREATMENT Rx

The relationship of change in alcohol use with prevention of subsequent problems has been well established. Treatment of alcohol use disorders should be based on the severity of potential or actual alcohol problems and tailored to meet the needs of individual patients. Separate advice and management approaches are suggested for nondependent at-risk or problem drinkers compared with individuals who are alcohol dependent (Table 32-4).

Treatment of At-Risk Drinkers

Evidence confirms that generalist physicians, in a cost-effective manner, can help patients reduce their alcohol intake and prevent subsequent alcohol-related problems by using brief (5 to 20 minutes), focused counseling techniques (brief interventions) that are well suited for primary care and other medical settings. The brief counseling strategy includes four main components: motivational techniques, feedback about the problems with alcohol use, discussion of the adverse effects of alcohol, and setting recommended drinking limits. Motivational techniques are designed to motivate patients to change their alcohol use behavior by identifying potential or actual problems with which their alcohol use is associated. Feedback about these problems can make it clear to the patient that the problems exist. For at-risk and problem drinkers who do not meet criteria for alcohol dependence, setting recommended drinking limits below at-risk levels (e.g., less than one drink per day for women and less than two drinks per day for men) is a realistic and suitable goal. Epidemiologic evidence suggests that drinking below these levels is less likely to be associated with problems. Several randomized clinical trials confirm that patients who receive brief interventions significantly decrease their alcohol intake, often to "safe" levels, and can decrease health care use as well.

TABLE 32-4 ADVICE FOR PATIENTS WITH ALCOHOL PROBLEMS

State your medical concern:
Be specific about your patient's drinking patterns and related health risks.
Ask: How do you feel about your drinking?

Agree on a plan of action:
Ask: Are you ready to try to cut down or abstain?
Talk with patients who are ready to make a change in their drinking about a specific plan of action.

For patients who are not alcohol dependent:
Advise the patient to cut down if drinking is at or above at-risk drinking amounts (see Table 32-1) and there is no evidence of alcohol dependence.
Ask the patient to set a specific drinking goal: Are you ready to set a drinking goal? Some patients choose to abstain for a period of time or for good; others prefer to limit the amount they drink. What do you think will work best for you?
Provide patient education materials and tell the patient: It helps to think about your reasons for wanting to cut down and examine what situations trigger unhealthy drinking patterns. These materials will give you some useful tips on how to maintain your drinking goal.

For patients with evidence of alcohol dependence:
Advise to abstain if:
- Evidence of alcohol dependence
- History of repeated failed attempts to cut down
- Pregnant or trying to conceive
- Contraindicated medical condition or medication

Refer for additional diagnostic evaluation or treatment.
Procedures for patient in making referral decisions:
- Involve your patient in making referral decisions.
- Discuss available alcohol treatment services.
- Schedule a referral appointment while the patient is in the office.

Treatment of Alcohol Dependence

Patients who meet criteria for alcohol dependence typically require more intensive services than do patients who meet criteria for at-risk drinking. Most patients can be managed in outpatient treatment settings, whereas patients with more severe alcohol dependence or comorbid problems initially may require inpatient management, specific counseling programs, and pharmacologic therapy. Before entering a formal program to maintain remission, many patients first require medical management of alcohol withdrawal. Professional organizations have published practice guidelines that provide useful recommendations for how to select among treatment options for patients with alcohol dependence.

Management of Alcohol Withdrawal

Many patients may not present for medical management of alcohol withdrawal and deal with it on their own. However, a substantial subset do present for alcohol withdrawal treatment. Patients with mild to moderate withdrawal generally can be managed safely as outpatients with close follow-up. Patients with moderate to severe withdrawal, as manifested by hypertension, tremor, and any mental status changes, especially patients with significant comorbid medical or psychiatric illnesses, generally are treated best as inpatients. Patients who have a history of severe withdrawal in the past (e.g., delirium tremens) or who have a history of alcohol withdrawal seizures also generally should be managed as inpatients. The three major goals of medical management of alcohol withdrawal are to minimize the severity of withdrawal-related symptoms; to prevent specific withdrawal-related complications, such as seizures and delirium tremens; and to provide referral to relapse prevention treatment.

A wide variety of medications have been evaluated for their effectiveness in managing the alcohol withdrawal syndrome (Table 32-5). Longer-acting benzodiazepines are preferred because they provide a smoother withdrawal. Shorter-acting benzodiazepines, such as oxazepam, may be indicated in individuals with severe liver disease. The most common approach is to administer a standing dose of a benzodiazepine, with additional medication being given "as needed" on the basis of withdrawal symptoms. The specific benzodiazepine and dose often depend on the experience of the prescribing physician and the characteristics of the patient, including the severity of withdrawal (higher doses are used if withdrawal is more severe), the presence of liver disease (patients with severe liver disease should receive lower doses or shorter-acting medications), and the response to prior doses of medication (higher doses are given if symptom control is inadequate; lower doses are given if adverse effects, such as oversedation, have occurred). In general, the amount of medication per dosing period is decreased gradually as the withdrawal syndrome abates. An individualized "symptom-triggered" dosing approach, in which benzodiazepines are administered on a dose-by-dose basis as guided by withdrawal symptoms, is safe and effective in certain patients and can reduce the total doses of benzodiazepines needed to treat withdrawal. β-Blockers (atenolol and propranolol), α-agonists (clonidine), and antiepileptics (carbamazepine) improve signs and symptoms of alcohol withdrawal but are viewed best as adjunctive medications to be used in addition to benzodiazepines.

Prevention of Relapse

Counseling Strategies Used by Alcohol Treatment Programs

Three commonly used psychotherapeutic techniques are motivational enhancement therapy, 12-step facilitation, and cognitive-behavioral coping skills. Two of these techniques are designed to give patients specific tools to help them avoid relapse to alcohol use. In motivational enhancement therapy, patients identify reasons for staying away from alcohol. The 12-step facilitation therapy uses the principles of AA to help patients focus their attention on abstinence. In cognitive-behavioral coping skills therapy, the patient identifies triggers to alcohol use and develops strategies to help deal with the triggers when they are present.

Project MATCH (Matching Alcohol Treatments to Client Heterogenicity) showed equivalence among three counseling approaches (cognitive-behavioral coping skills therapy, motivational enhancement therapy, or 12-step facilitation therapy) to treat alcohol dependence. At 1-year follow-up, most enrolled patients either remained abstinent or significantly decreased their alcohol use.

Self-Help Groups

Self-help groups such as AA and Rational Recovery are an important source of support and treatment for many patients with alcohol dependence. AA has

TABLE 32-5 MEDICATIONS FOR THE TREATMENT OF ALCOHOL DEPENDENCE*

MEDICATION	DOSE AND ROUTE	FREQUENCY	EFFECTS	MAJOR COMMON ADVERSE EFFECTS
ALCOHOL WITHDRAWAL				
Benzodiazepines‡				
Chlordiazepoxide*	25-100 mg, PO/IV/IM‡	Every 4-6 hr	Decreased severity of withdrawal; stabilization of vital signs; prevention of seizures and delirium tremens	Confusion, oversedation, respiratory depression
Diazepam†	5-10 mg, PO/IV/IM‡	Every 6-8 hr		
Oxazepam†	15-30 mg, PO‡	Every 6-8 hr		
Lorazepam†	1-4 mg, PO/IV/IM‡	Every 4-8 hr		
β-Blockers				
Atenolol	25-50 mg, PO	Once a day	Improvement in vital signs Reduction in craving	Bradycardia, hypotension
Propranolol	10-40 mg, PO	Every 6-8 hr		
α-Agonists				
Clonidine	0.1-0.2 mg, PO	Every 6 hr	Decreased withdrawal symptoms	Hypotension, fatigue
Antiepileptics				
Carbamazepine	200 mg, PO	Every 6-8 hr	Decreased severity of withdrawal; prevention of seizures	Dizziness, fatigue, red blood cell abnormalities
PREVENTION OF RELAPSE				
Disulfiram†	125-500 mg, PO	Daily	Decreased alcohol use among those who relapse	Disulfiram-alcohol reaction, rash, drowsiness, peripheral neuropathy
Naltrexone†	50 mg, PO 380 mg, IM	Daily Every 4 wk	Increased abstinence, decreased drinking days	Nausea, abdominal pain, myalgias-arthralgias
Acamprosate†	666 mg, PO	Three times a day	Increased abstinence	Diarrhea

*Most commonly used medications listed.
†Currently approved by U.S. Food and Drug Administration for the indication noted.
‡Dose and routes given for standard fixed-dose regimens, which include dose tapers over time.

TABLE 32-6 OVERVIEW OF TREATMENT APPROACH FOR PATIENTS WITH ALCOHOL PROBLEMS

Evaluate all patients
- For patterns of problem alcohol use (Table 32-1)
- For alcohol-related complications, if indicated (Table 32-2)
- With use of data collected from history, physical examination, and laboratory testing (Table 32-3)

For at-risk and nondependent problem drinkers
- Advise to decrease alcohol use to below at-risk levels (Table 32-4)
- Advise patients who cannot decrease use to below at-risk levels to abstain

For patients who are alcohol dependent
- Assess for need for withdrawal management medications (Table 32-5)
- Refer to an alcohol treatment program
- Consider medication to prevent relapse (Table 32-5)

the advantage of being widely available throughout the United States and is free of charge. The overall approach to treatment is based on the 12 steps for maintaining abstinence and dealing with the various effects of alcohol. AA meetings can be either "open" to anybody in the community or "closed" for active members only. The meetings vary in format, size, location, and demographic makeup. In counseling patients about attending AA, it is important for physicians to make them aware that variations in the nature of specific meetings, especially location and demographics of participants, require patients to be willing to attend more than one meeting site on a trial basis so that they find a comfortable setting.

Research of the effectiveness of AA has been limited, and there are no large controlled studies. Indirect evidence suggests, however, a significant improvement in alcohol use behaviors.

Pharmacotherapy to Prevent Relapse to Alcohol Use

The addition of medication to enhance the effectiveness of counseling therapies has been the subject of research for the past 40 years. As the neurobiology of alcohol use disorders has become more clearly understood, the potential to develop medications that may promote abstinence or decreased alcohol use has grown. Three medications—disulfiram, naltrexone, and acamprosate—are approved for the treatment of alcohol dependence in the United States[1] (see Table 32-5).

Disulfiram

Disulfiram is designed to prevent alcohol use by causing a severe adverse reaction when patients use alcohol. The disulfiram reaction, which includes flushing, nausea, vomiting, and diarrhea, is mediated by the inhibition of alcohol dehydrogenase and the resulting increase in serum levels of acetaldehyde and acetate after ingestion of alcohol. Disulfiram also affects monoamine metabolism, and the alcohol-disulfiram reaction may be related to changes in central monoamine functioning. Although disulfiram offers little benefit to most patients, it is effective in reducing alcohol intake in highly motivated patients who are supervised in an alcohol treatment program.

Naltrexone

Naltrexone is thought to decrease alcohol use by diminishing the euphorigenic effects of alcohol and by decreasing craving in alcohol-dependent patients. Randomized, placebo-controlled trials generally have shown that alcohol-dependent patients who receive naltrexone (50 mg/day) are more likely to decrease their alcohol use or remain abstinent compared with patients who receive placebo,[2] and the effects persist after discontinuation of treatment, although one randomized trial did not show benefit in male veterans with severe alcohol dependence. Although most studies of naltrexone were performed in a specialty alcohol treatment setting and observed subjects for only 10 to 12 weeks, one study demonstrated that naltrexone can be effective in primary care settings in patients who were observed for up to 34 weeks.[3] Side effects of naltrexone are infrequent, most notably self-limited nausea in about 10% of patients. Dose-related hepatotoxicity has been reported in patients treated for obesity with high-dose naltrexone (300 mg/day). Mild liver enzyme abnormalities are not a contraindication to naltrexone, but patients should be followed with repeated liver enzyme studies. Patients with acute hepatitis or liver failure should not use naltrexone. In addition to the oral naltrexone, a newer long-acting injectable form of naltrexone was approved by the U.S. Food and Drug Administration (FDA) in 2006.[4] Injectable naltrexone is typically administered at a dose of 380 mg intramuscularly every 4 weeks. Before beginning naltrexone, it is important to be sure that the patient is not opioid dependent in order to avoid a potentially severe opioid withdrawal reaction. Complete opioid abstinence for at least 7 to 10 days is recommended. Adverse reactions seen most commonly in patients who receive injectable naltrexone include injection site reactions (e.g., induration, itching) and symptoms such as nausea and headache, which are generally self-limited.

Acamprosate

Approved by the FDA in 2004, acamprosate (calcium acetylhomotaurinate) has been identified as an effective agent for treatment of alcohol dependence. The precise mechanism of action of acamprosate is uncertain, but it may be related to its effects on neuroexcitatory amino acids and the inhibitory GABA system. In a randomized, placebo-controlled clinical trial, subjects who received acamprosate were more likely to remain abstinent compared with

subjects who received placebo.[5] Side effects are minimal and typically include diarrhea. Like naltrexone, acamprosate is given as an adjunctive therapy to psychological treatments for alcohol dependence.

Other Pharmacologic Approaches to Prevent Relapse

There has been much interest in evaluation of the effectiveness of combinations of drug therapies to treat alcohol dependence. One study of 160 patients suggested that the combination of naltrexone and acamprosate was more effective than either medication alone. A larger federally funded study that enrolled 1383 subjects, Project COMBINE, examined naltrexone and acamprosate alone and in combination with two different psychological therapies to see which combination of pharmacologic and behavioral therapies is most effective.[6] The behavioral therapies were medical management, which was designed to approximate counseling that can be provided in primary care and other medical settings, and combined behavioral intervention, which incorporated counseling techniques that are provided in alcohol treatment specialty settings. Results from this study demonstrated that patients receiving medical management with naltrexone, combined behavioral intervention, or both fared best, lending further support to the idea that alcohol-dependent patients can be effectively treated in primary care and other medical settings. Interestingly, acamprosate was not shown to be effective in this study.

Topiramate, a fructopyranose derivative, has been shown to be an effective treatment of alcohol dependence in randomized clinical trials at a dose of up to 300 mg/day.[7] Other medications that have shown promise include ondansetron, bromocriptine, and sodium valproate. Other drugs have shown possible benefits in patients with concurrent depression (e.g., fluoxetine) or anxiety (e.g., buspirone) or no effect (e.g., lithium).

FUTURE DIRECTIONS

To date, most studies have focused on shorter-term outcomes, from a few months to a year. It is important to understand more clearly what happens to these patients over time, especially the need for "booster sessions" to sustain improvements provided by brief interventions. Newer pharmacologic therapies may help many patients.

DRUG ABUSE AND DEPENDENCE

ROGER D. WEISS

DEFINITION

The terms *drug abuse* and *drug dependence* refer to a clinical syndrome characterized by the following statement from the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*: "The essential feature of dependence is a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues substance use despite significant substance-related problems." There is no single pathognomonic symptom that is diagnostic of drug dependence. Rather, the syndrome of drug dependence as described in the text above is a series of seven symptoms, of which the individual needs to meet three in the same 12-month period to warrant a diagnosis of dependence (Table 33-1). Several points are important to keep in mind when considering the diagnosis of drug dependence.

The criteria for the diagnosis are the same regardless of the substance used. Thus, the criteria for opioid dependence are the same as those for nicotine dependence and cocaine dependence, although different drugs are more likely to produce different symptoms.

The diagnostic term *drug dependence* should only be used with people whose drug use is problematic; tolerance and physical dependence are neither necessary nor sufficient for a diagnosis of drug dependence. If someone is using legitimately prescribed medications as intended (e.g., opioids for chronic pain or benzodiazepines for panic disorder), and those medications are helping the person to function better, that person will not meet criteria for drug dependence, even if the person is tolerant to the medication and is physically dependent.

Finally, the 5th edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* may no longer distinguish between abuse and dependence, using the term *substance abuse disorder* instead. However, that decision has not yet been finalized.

EPIDEMIOLOGY

Use of illicit drugs and nonmedical use of prescribed drugs is quite common. In 2009, approximately 22 million Americans reported using an illicit drug in

TABLE 33-1 DIAGNOSTIC CRITERIA FOR DRUG DEPENDENCE AND DRUG ABUSE

"A maladaptive pattern of substance use, leading to clinically significant impairment or distress."

DEPENDENCE (≥3 IN 12-MONTH PERIOD)

1. Tolerance
2. Withdrawal
3. The substance is often taken in larger amounts for a longer period than intended
4. Unsuccessful efforts or a persistent desire to cut down or to control substance use
5. A great deal of time is spent in activities necessary to obtain the substance or to recover from its effects
6. Important social, occupational, or recreational activities given up or reduced because of substance use
7. Continued substance use despite knowledge of having had persistent or recurrent physical or psychological problems that are likely to be caused or exacerbated by the substance

ABUSE (≥1 IN A 12-MONTH PERIOD)

1. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home
2. Recurrent substance use in situations in which it is physically hazardous
3. Recurrent substance-related legal problems
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance

Never met criteria for dependence

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington DC: American Psychiatric Association; 1994.

the previous month, representing approximately 9% of the population: when asked about their substance use in the past month, 17 million people reported using marijuana, 7 million reported using potentially psychoactive prescription drugs nonmedically, 2 million people used cocaine, and 1 million people used hallucinogens; in fact, 10% of youths aged 12 to 17 years reported using an illicit drug in the past month. Drug abuse produces substantial medical morbidity and mortality as well as tremendous social and economic costs.

PATHOBIOLOGY

Drug abuse and dependence are complex disorders involving the interaction between the pharmacology of a specific drug, an individual's genetic makeup, psychological strengths and weaknesses, environmental circumstances, and societal influences such as physical and perceived drug availability, legal status and cost of the drug, religious and cultural mores, and presence of alternative rewarding activities. Thus, one can conceptualize the etiology of drug abuse by employing the public health model frequently cited when studying infectious disease, that is, as an interaction among the host (i.e., the potential drug user), the agent (a specific drug in this case, as opposed to an infectious microorganism), and the environment (the person's family life, peer group, and the social, cultural, and religious attitudes toward use of that substance).

The Host

A host factor that is well known to heighten vulnerability to drug abuse problems is a positive family history of a substance use disorder, which has been shown to increase the likelihood of development of both alcohol and drug dependence. Twin studies and adoption studies have shown that both genetic and environmental factors contribute to this vulnerability, although the precise nature by which this occurs is still unknown and a subject of active research. One area of great research interest relates to whether people can be vulnerable to drug dependence in general (e.g., as a result of a risk-taking temperament or poor decision making) or whether they are at high risk to abuse particular substances (perhaps because of a highly reinforcing response to a specific drug).

Psychiatric illness and personality disorders have been shown to influence the likelihood of developing drug abuse problems. For example, the presence of conduct disorder in childhood and adolescence and antisocial personality disorder in adulthood have both been shown to predispose to subsequent drug abuse problems. Psychiatric disorders such as mood disorders are frequently found in people with drug abuse problems. However, it is important to note that the presence of these two disorders in the same person does not necessarily imply causation, even if one of the disorders manifests first.

In addition to the risk factors mentioned previously, certain individual protective factors may reduce the likelihood of an addictive disorder. Individuals who have positive familial relationships, success in academic activities, and meaningful religious affiliation have a lower likelihood of developing drug abuse problems. The fact that many people have a mixture of risk and protective factors speaks to the complex etiologic nature of drug abuse problems.

The Agent

Most drugs of abuse are inherently reinforcing; animals typically will self-administer most of the commonly abused drugs. Not all drugs are equally reinforcing in general, however, and there is a great deal of individual variation in drug preference. Some people like the stimulating effects of drugs such as cocaine and amphetamine, whereas others experience that level of stimulation as extremely uncomfortable. Some people like the relaxation induced by drugs such as marijuana and sedative-hypnotics, whereas others feel deadened and overly slowed down by these drugs. Although some people gravitate toward particular drugs of abuse because of their specific pharmacologic properties, other will use a variety of drugs indiscriminately, based on level of availability; some of these people are primarily seeking to alter their current emotional state, regardless of the direction in which it is changed. The reinforcing properties of many drugs of abuse appear to be mediated through dopaminergic pathways, although other neurotransmitters, including γ-aminobutyric acid (GABA), serotonin, and norepinephrine are also involved in mediating drug-induced reinforcement.

The Environment

The third critical factor in the development, maintenance, and (perhaps) cessation of drug abuse is the environment in which the use occurs. Drug use does not occur in a vacuum. Rather, many societal factors, including legal status, availability, price, perception of dangerousness, social desirability, peer group, and religious beliefs influence behavior relating to substance use. Drug availability is known to be a substantial influence on likelihood of substance use. For example, alcohol consumption has been shown to increase when the hours during which alcohol can be sold are extended. The restriction of alcohol availability by restricting hours of sale or by increasing its cost through taxation, in turn, reduces consumption. Illicit drugs are, of course, by definition less available than alcohol or tobacco. A major factor that influences use of these agents is the potential user's perception of the drug's safety, social cachet (or lack thereof), likelihood of incurring legal consequences, and peer group behavior. Treatment research has shown that environmental influences can have a powerful effect on drug use: studies have shown, for example, that offering an alternative positive reward (e.g., a voucher that can be exchanged for desired goods and services such as movie tickets or clothes) in response to abstaining from drugs may help drug-dependent individuals overcome their severe craving and reduce their substance use. In fact, this type of treatment approach, based on the use of motivational incentives for abstinence, has been shown to be one of the most powerful treatment interventions available for the treatment of drug dependence. The responsiveness of drug-dependent individuals to environmental contingencies demonstrates the importance of appreciating the complexity of the interaction among the individual, the drug, and the environment in the determination of drug use.

CLINICAL MANIFESTATIONS

Medical Complications Related to Drug Abuse and Dependence

Drug abuse is associated with significant medical morbidity and sometimes with mortality. Medical complications related to drug abuse are often directly related to the pharmacology of the abused agent, for example, the vasoconstrictor properties of cocaine; drug-specific complications are described later in the sections focusing on particular drugs of abuse.

In addition to these drug-specific sequelae, however, many medical complications incurred by drug-dependent patients occur not as a result of the particular drug being abused. Rather, serious complications may occur as a result of three factors that cut across many of the drugs of abuse: (1) paraphernalia, particularly unsterile needles; (2) adulterants; and (3) lifestyle issues.

Paraphernalia

Some of the most serious medical problems that occur in individuals with drug abuse and dependence occur as a result of the route of administration rather than from the actual drug being used. The use of unsterile needles, particularly if shared with other drug users, can lead to a variety of localized and systemic infections, some of which can be life-threatening. Skin infections and cellulitis are relatively common among injection drug users. Systemic infections related to needle use are often quite serious; individuals who inject drugs may develop infective endocarditis (Chapter 76). Other relatively common infections among injection drug users include hepatitis B, hepatitis C, and HIV infection.

Adulterants

Drugs that are purchased and sold illicitly are often adulterated or "cut" with other similar-looking products, with the intention of increasing the dealer's profit margin. For example, other white powdery substances are typically added to cocaine and heroin during the dealing process, to dilute their purity. Some of these adulterants can, in turn, cause medical problems. At times, these complications occur because of the combined toxicity of the adulterant and the route of administration. Thus, for example, a patient may have a granuloma in the lung or liver as a result of talc use; talc is commonly added to street heroin and can also cause difficulties in users who crush talc-containing pharmaceutical tablets (e.g., opioids) and then inject them. Other common adulterants in street drugs include quinine (frequently used with heroin) and lidocaine (often added to cocaine), but such toxic materials as strychnine and ground glass have been found in samples of street drugs, leading to serious medical sequelae.

Lifestyle Issues

Many drug-dependent patients expose themselves to multiple risks due to intoxication, participating in dangerous illegal activities, and associating with potentially violent people. As a result, these individuals experience a high rate of traumatic injuries and are at greater risk of being victims of

assault, homicide, or suicide. Suicide is far more common among people with substance abuse problems than among the general population; this may be related to a combination of the effects of acute intoxication, the high prevalence of depression among drug-dependent patients, and the higher rate of antisocial personality disorder in this population, which is associated with a propensity toward impulsiveness, risk taking, and violence. Although it is well known that intoxication can lead to motor vehicle crashes, intoxication can also serve as a risk factor for becoming a victim of someone else's vehicle; one study reported that one third of pedestrians who are killed by motor vehicles have alcohol in their blood, perhaps a reflection of the combination of risk taking, poor judgment, and impaired motor coordination that can occur during periods of intoxication.

TREATMENT

Rx

General Treatment Principles

Drug abuse and dependence represent a relatively heterogeneous group of disorders, based on type of drug or drugs used, frequency and amount of use, severity of medical, behavioral, and social consequences, presence and severity of comorbid medical and psychiatric illness, and motivation to change. Treatment thus requires a careful medical and psychiatric assessment, including a detailed substance use history and laboratory testing. It is often helpful to enlist the help of a family member or significant other (with the patient's permission) in obtaining historical information. Intoxication and withdrawal syndromes need to be treated acutely; longer-term treatment involves helping the patient to reduce or (ideally) abstain from substances of abuse and thus improve overall functioning.

Among the common drugs of abuse, medications with approval by the U.S. Food and Drug Administration (FDA) are only available for opioids. However, researchers are actively studying a number of compounds for the treatment of other drugs of abuse, particularly stimulants and marijuana. Behavioral treatments are critically important in the treatment of substance use disorders. A number of behavioral treatments have a substantial evidence base supporting their efficacy; these include cognitive-behavioral therapy, motivational enhancement therapy, contingency management (also referred to as *motivational incentive*) therapy, 12-step facilitation therapy, and behavioral couples therapy. In addition to professional treatment, peer support groups such as the 12-step-oriented Alcoholics or Narcotics Anonymous and non-12-step groups such as SMART Recovery can be extremely helpful in facilitating recovery from drug abuse problems.

MAJOR DRUGS OF ABUSE

Opioids

For centuries, opioids have been a core part of the medical pharmacopoeia, primarily because of their capacity to treat pain, but also because of their antitussive and antidiarrheal properties. Unfortunately, opioids are also powerful euphoriants and thus have substantial abuse liability. Although opium itself has been used for centuries, the isolation of morphine and codeine from opium in the 19th century, along with the introduction of the hypodermic needle, led to the increased prevalence of intravenous opioid use. Ironically, heroin was introduced near the end of the 19th century as a treatment for morphine addiction.

Opioids can be divided into four categories: (1) natural opium alkaloids, including opium, morphine, and codeine; (2) semisynthetic derivatives of morphine, including heroin and oxycodone; (3) synthetic opioids that are not derived from morphine, including methadone and meperidine; and (4) opioid-containing preparations such as elixir of terpin hydrate.

EPIDEMIOLOGY

Opioid dependence represents a significant public health problem and accounts for more admissions for substance use disorder treatment than any substance other than alcohol. In the past decade, there has been a shift in the epidemiology of opioid abuse, however, with a reduction in heroin use and an increase in the abuse of opioid analgesic drugs; the latter has occurred as a result of either misuse of prescription opioids or illicit use of these agents. Approximately 600,000 people reported using heroin in 2009, with 180,000 trying the drug for the first time. During the same year, over 12 million people either misused prescription opioids or used them illicitly, with 2 million doing so for the first time; opioids are currently the most commonly misused prescription drugs. Most people who use opioid analgesics in this way report that they obtained them from a friend or relative. It is thus likely that a portion of these people might, for example, have used a relative's opioid for the treatment of a temporary painful condition such as a migraine headache. However, the number of people seeking treatment for dependence on opioid analgesics has increased dramatically in the past decade.

PATHOBIOLOGY

Opioids are readily absorbed when taken orally, intranasally, or by smoking or injection. Heroin, which is almost immediately converted to morphine in the liver, is most commonly injected but may be smoked or used intranasally.

Opioids work by binding to specific opioid receptors and then exerting their activity. Three major subtypes of opioid receptors have been identified and well described for many years. Most of the commonly abused opioids bind as agonists to the μ-receptor and typically produce the effects most commonly associated with opioids: miosis, respiratory depression, analgesia, euphoria, and drowsiness. Opioids that bind to the κ-receptor, unlike μ-receptor agonists, often produce dysphoria rather than euphoria. The other two receptors, δ- and N/OFQ-receptors, do not appear to play a known significant role in opioid dependence.

Opioid analgesics are ordinarily taken by the oral route, but they may be altered to be used through a different route of administration. This is particularly common with the extended release preparations, which may be altered by chewing the pill (facilitating a rapid release of the opioid medication) or by crushing the pill, dissolving it in water, and then injecting it or using it intranasally.

CLINICAL MANIFESTATIONS

The initial response to the administration of heroin, particularly when used intravenously, is a "rush," often described as orgasmic, lasting 30 to 60 seconds. This sensation is generally followed by a profound sense of relaxation that is sometimes referred to as being "wrapped in warm cotton." During this period, the user generally feels drowsy and may be seen to be "nodding," with mental clouding and a sense of tranquility. A reduction in respiratory rate occurs, along with miosis, reduced contractility of smooth muscle, and reduced secretions in the stomach, pancreas, and biliary tract. Thus, constipation and urinary hesitancy may occur. Itching is commonly seen during opioid intoxication. Many people experience nausea and vomiting in their initial use of opioids, although tolerance tends to develop to this effect over time. Tolerance also occurs to some other effects rather quickly, particularly the analgesic, respiratory depressant, and euphoriant properties of opioids. In contrast, relatively little tolerance occurs to constipation or to pupillary constriction. It is important to be aware, then, that miosis is a manifestation of opioid use, but it is not diagnostic of opiate overuse or intoxication.

Physical Dependence

Physical dependence on opioids leads to a characteristic withdrawal syndrome, the key signs of which include elevated heart rate and blood pressure, mydriasis, abdominal cramps, sweating, gooseflesh, rhinorrhea, lacrimation, and gastrointestinal distress, particularly diarrhea, nausea, and vomiting. Insomnia is common, particularly difficulty falling asleep; this is often the most long-lasting complaint among people who experience opioid withdrawal. Yawning, muscle twitches, and difficulty with body temperature regulation are also commonly seen. The severity of withdrawal can be highly variable, depending on the dose of opioids taken, the length of time that they have been taken, and individual factors. For short-acting opioids such as heroin and hydrocodone, the earliest stages of withdrawal typically occur approximately 6 to 12 hours after the last use. Peak symptoms tend to occur 48 to 72 hours after the last dose, and most clinical symptoms usually resolve within 7 to 10 days. For longer-acting opioids such as methadone, each of these time periods associated with withdrawal from short-acting opioids should be approximately doubled or tripled.

Other Medical Complications

The most common serious medical complications that occur from opioid use are typically related to factors other than the opioids themselves, particularly needle use and adulterants; these were discussed previously. Common medical problems among those dependent on heroin include hepatitis B, hepatitis C, infective endocarditis, talc granulomatosis, HIV infection, cellulitis, and abscesses, all typically related to needle use.

An important noninfectious complication that has been reported with opioid abuse is alteration of the cardiac conduction system, with a prolongation of the QT interval; this can lead to potentially serious arrhythmias,

including torsades de pointes. This complication has been particularly noted with the long-acting opioid L-α-acetylmethadol (LAAM) and with methadone.

Chronic pain is commonly seen among opioid-dependent individuals, not just those who have received opioids for the treatment of pain. Pain can occur in opioid-dependent individuals for numerous reasons. In addition to the possibility that a chronic painful condition led to the use of opioids in the first place, those dependent on opioids are more likely to experience accidents, violence, and other forms of physical trauma that could produce chronic pain. There is also some evidence that chronic opioid use may lead to hyperalgesia, although there is some controversy regarding this issue. As with all substance use disorders, psychiatric illnesses (particularly mood disorders) are more common in opioid-dependent patients than in the general population. Moreover, it is important to note that the use of multiple drugs is extremely common in patients with opioid dependence, particularly among those using heroin. Indeed, the use of more than one drug is typically the rule rather than the exception in most substance use disorders.

TREATMENT Rx

Opioid Withdrawal

Opioid detoxification can be accomplished by switching patients from their current drug of abuse (e.g., heroin, hydrocodone) to methadone or buprenorphine and then tapering that medication. Although the details of accomplishing this vary, one method commonly used in hospital settings is to administer methadone 10 mg orally whenever a patient experiences objective signs of opioid withdrawal (e.g., mydriasis, tachycardia, hypertension, and sweating). This process can be repeated every 2 to 4 hours for 24 hours after the initial dose; the total amount of methadone given in that 24-hour period is the "stabilization dose," which should not ordinarily exceed 40 mg. The stabilization dose is then reduced by 5 mg a day until the detoxification is completed.

Buprenorphine can also be used successfully for opioid detoxification; patients who demonstrate objective signs of opioid withdrawal (often measured with a standardized withdrawal severity scale) can be stabilized on buprenorphine over a 1- to 2-day period; the subsequent taper from buprenorphine may occur either right away or after a period of stabilization on buprenorphine. The dose of buprenorphine will depend on whether the medication will be used for a brief, several-day detoxification or for longer-term stabilization or maintenance treatment.

Longer-Term Opioid Dependence Treatment

There are three effective medications that are approved by the FDA for the treatment of opioid dependence: methadone (a full opioid agonist), buprenorphine (a partial agonist), and naltrexone (an opioid antagonist). Methadone has been used successfully for both detoxification from opioids and maintenance treatment for many years. Unlike buprenorphine and naltrexone, which can be prescribed by physicians in their offices (although physicians wishing to prescribe buprenorphine for the treatment of opioid dependence must receive specialized training and certification to do so), methadone is available for the treatment of opioid dependence only in specially licensed treatment programs. Methadone is a long-acting μ-receptor agonist with a slow onset of peak effects (typically approximately 2 to 6 hours) and a slow offset of action, allowing for once-a-day administration. Methadone reduces opioid craving and induces cross-tolerance, thus blocking or attenuating the effects of other opioid use. Although the therapeutic dose of methadone for a particular individual may vary, doses of 60 mg or higher have typically been shown to be more effective than lower doses; there is some evidence that even higher doses (e.g., 80 mg a day or more) may be more effective than 60 mg. Methadone treatment has been shown to reduce opioid use, increase employment, decrease criminal behavior, and reduce the rate of development of HIV infection.

When a patient enrolled in a methadone treatment program experiences pain (e.g., postoperatively) requiring opioid analgesia, the patient should continue to receive the baseline methadone maintenance treatment dose for the addiction and should receive a different opioid for treatment of the pain (Chapter 29); before administering methadone, it is a good idea to confirm the methadone dose with the patient's treatment program whenever possible. The fact that the patient is receiving methadone every day does not obviate the need for opioid analgesia, however. In fact, many patients receiving methadone treatment for opioid dependence will require a dose of opioids that is relatively high as a result of cross-tolerance to other opioid drugs.

The Drug Addiction Act of 2000 revolutionized the treatment of opioid dependence by enabling the approval of the partial opioid agonist buprenorphine for the treatment of opioid dependence and allowing treatment with buprenorphine to be administered in physicians' offices rather than only in specialized opioid treatment programs. To prescribe buprenorphine, physicians must apply to the Substance Abuse and Mental Health Services Administration (SAMHSA) for a waiver that allows them to prescribe buprenorphine, after taking an 8-hour training course on buprenorphine. At the time of this writing, physicians may treat up to 100 patients with buprenorphine in their office practice. Buprenorphine, a partial μ-agonist and κ-antagonist, has a more favorable safety profile than methadone because of its partial agonist properties. Respiratory depression, which can be induced by full agonists, and which is responsible for some overdose deaths, is far less likely to occur with buprenorphine because its partial agonist properties cause a plateau of opioid effects as the dose increases. Buprenorphine is administered sublingually for the treatment of opioid dependence either as buprenorphine alone (sometimes referred to as the "mono" product) or (more commonly, in the United States) as a combination product of buprenorphine and naloxone; the naloxone is added to discourage users from dissolving the tablet and injecting the medication because the naloxone in the combination product will precipitate withdrawal when injected. Buprenorphine has been shown to be effective for both opioid detoxification and for maintenance treatment. A randomized trial has shown that extended treatment with buprenorphine-naloxone for 12 weeks improved outcome compared with short-term detoxification in opioid-addicted youth (aged 15 to 21 years). Typical doses of 12 to 16 mg of sublingual buprenorphine per day appear to be as effective as methadone in doses up to approximately 60 mg a day. However, individuals who require much higher doses of methadone may respond better to that agent than to buprenorphine.

Naltrexone, a pure opioid antagonist, blocks the effects (including euphoria) of opioids. As a result, individuals taking naltrexone should have a reduced desire to use opioids because the latter drug will have no desired effect. When used orally (50 mg/day) or in its long-acting form (380 mg intravenously every 4 weeks), naltrexone is highly effective at suppressing illicit opioid use. However, naltrexone suffers from very low acceptability; few patients are interested in being treated with naltrexone. Moreover, among those who initially accept this treatment, the dropout rate is extremely high. Nevertheless, naltrexone can be a useful medication for patients who are willing (either as the result of external pressure or for internal motivation) to use it.

Methadone, buprenorphine, and naltrexone are not designed to be delivered alone but should be given along with counseling to be effective. It has been well demonstrated that the administration of methadone in the absence of counseling is an inadequate treatment approach; less is known about the optimal combination of buprenorphine and counseling. One study demonstrated that counseling delivered within a medical office setting can be quite effective in conjunction with buprenorphine treatment, suggesting that general physicians who are trained to use buprenorphine can effectively treat at least a portion of patients with opioid dependence in their offices with a combination of buprenorphine and counseling.

Central Nervous System Stimulants: Cocaine and Amphetamines

The two most important central nervous system stimulants, cocaine and amphetamine (including methamphetamine), are derived from different sources; the former is extracted from coca leaves, whereas the latter is a synthetic compound. However, both induce similar psychoactive activity when taken illicitly and can produce similar adverse consequences. Amphetamine has been used over the years to treat obesity and to combat fatigue and depression. Cocaine is still used as a topical anesthetic for otolaryngologic surgery. Ironically, its vasoconstrictor action, which is responsible for many of the cocaine-related medical complications described later, can be valuable for surgeons because of the resultant reduction of blood flow in the operating field. Although cocaine was not extracted from the coca leaf until the 19th century, coca leaves have been chewed for more than 1500 years for medicinal and religious purposes, as well as to combat work-related fatigue. Sigmund Freud was one of the foremost advocates of cocaine, both extolling its psychoactive properties and discovering its ability to relieve pain, thus eventually leading to its discovery as the first local anesthetic. Cocaine was seen in the late 19th century as a "cure-all" and was included in numerous patent medicines as well as in Coca-Cola. The Harrison Narcotic Act of 1914 restricted the use of cocaine, and the drug was not widely used until the late 1970s, when there was a resurgence in cocaine use in the United States.

Like cocaine, amphetamine was synthesized for the first time in the late 19th century. It was used for clinical purposes for the first time in the 1920s. Reports of amphetamine abuse first occurred in the 1930s, with intermittent epidemics since that time. In recent years, methamphetamine abuse has been particularly prevalent and worrisome in the United States, with particularly high concentration of its use in the Midwestern and Western states, including Hawaii.

Cocaine can be used either intranasally, by intravenous injection, or by smoking. Cocaine hydrochloride, which is the form of the drug used in medical therapeutics, is a water-soluble compound that can be used intranasally ("snorted") or injected. Adding an alkaline compound such as baking

soda to an aqueous solution of cocaine hydrochloride produces a rocklike compound known as *crack,* which can be smoked. Smoking cocaine produces the most rapid onset of intoxication (6 to 10 seconds) and the shortest period of drug effect (10 to 15 minutes). Methamphetamine can also be used in multiple ways—either orally, by smoking, or intravenously. Methamphetamine effects last much longer than those produced by cocaine; psychiatric symptoms such as paranoia that typically last only a matter of hours in cocaine users may persist for days to weeks after methamphetamine use and occasionally may result in a chronic psychotic state.

EPIDEMIOLOGY

Approximately 37 million Americans have used cocaine during their lifetime. In 2009, just under 5 million people used cocaine; 1.6 million people, or 0.7% of the population, reported using cocaine in the past month. Of these past-month cocaine users, 30% (492,000) used crack, an increase from 2008. There were 600,000 new users in 2009, a number that has been in decline since 2002. Cocaine had the third highest rate of drug abuse or dependence in 2009 and was the second most common drug associated with a recent treatment episode; cocaine use is also associated with 28% of emergency room visits associated with drug abuse.

Other stimulant use is less common; approximately 22 million Americans have used stimulants nonmedically during their lifetime, with 12.8 million lifetime methamphetamine users. Methamphetamine use in the past month was reported by 500,000 people in the United States in 2009, a number comparable to the number of past-month crack cocaine users.

PATHOBIOLOGY

Both cocaine and amphetamine increase the accumulation and activity of specific neurotransmitters in the synaptic cleft, including dopamine, norepinephrine, and serotonin. Cocaine is believed to exert this effect by binding to the dopamine transporter. Increased dopaminergic activity, particularly in the nucleus accumbens, is thought to be responsible for the reinforcing effects of cocaine. Amphetamines appear to increase the level of dopamine in the synaptic cleft primarily by stimulating presynaptic dopamine release as opposed to reuptake blockade.

CLINICAL MANIFESTATIONS

Both cocaine and amphetamines reliably produce euphoria, wakefulness, a sense of initiative, increased self-confidence (sometimes to the point of grandiosity), and in some instances, sexual stimulation. With higher doses, users may feel "wired," a syndrome characterized by anxiety, irritability, and perhaps paranoia. Withdrawal from either of these agents leads to opposite effects from those of intoxication: increased appetite, hypersomnia, and depression, which can occasionally be serious. Medical complications related to cocaine use are related to a combination of cocaine's stimulant activity (increased heart rate and blood pressure) and its vasoconstrictor properties. Local complications that result from the drug's vasoconstrictor activity include ulcerations of the nasal mucosa, perforation of the nasal septum, and decreased pulmonary diffusion capacity. Systemic complications include myocardial infarction, intracranial hemorrhage, grand mal seizures (as a result of intoxication, not withdrawal), and ventricular tachyarrhythmias, which may be responsible for sudden death. Physicians seeing a patient in an emergency room for an unexplained seizure should consider drug abuse as a potential cause (not only cocaine, but also phencyclidine and meperidine intoxication may lead to seizures, as can sedative-hypnotic or alcohol withdrawal). A serum or urine toxicology screen may thus be an important diagnostic tool in such a situation.

TREATMENT Rx

The treatment of central nervous system stimulant abuse and dependence primarily consists of behavioral therapies, including individual and group therapy, and self-help groups. Specific forms of treatment, such as cognitive-behavioral therapy, individual drug counseling using a 12-step-oriented disease model, and a behavioral treatment in which patients are reinforced for positive outcomes (e.g., drug-free urine screens), have been found to be successful. A great deal of research has been conducted in search of an effective pharmacotherapeutic treatment for stimulant dependence, but there is as yet no medication that has consistently been found to be effective enough to warrant approval by the FDA for this purpose.

Sedative-Hypnotic and Anxiolytic Drugs

Benzodiazepines and other sedative-hypnotic and anxiolytic medications such as barbiturates and zolpidem are frequently prescribed for the treatment of anxiety and sleep difficulties. Although different classifications of these drugs have very different chemical structures, they are grouped together according to their therapeutic applications. Most of these drugs act at the γ-aminobutyric acid type A ($GABA_A$) receptor and can cause physical dependence and both dispositional and pharmacodynamic tolerance. According to epidemiologic studies, approximately 9 million people, or 3.6% of the population aged 12 years and over, have used a sedative-hypnotic drug nonmedically.

Because the benzodiazepines are far and away the most commonly prescribed sedative-hypnotics, they are also the most widely abused. There are two major patterns of benzodiazepine abuse. Many people who ultimately abuse these medications have initially received a legitimate benzodiazepine prescription for the treatment of anxiety or insomnia. However, a combination of tolerance and decreased effectiveness of the agent over time may lead some people to increase their dose on their own. In such circumstances, attempts by the physician to taper the person off of the medication can be very difficult.

A second pattern of benzodiazepine abuse occurs among individuals who are using other drugs of abuse, most commonly opioids or stimulants. For example, many individuals who are dependent on heroin or other opioids may use benzodiazepines as a means of either enhancing the opioid effect or buffering symptoms of opioid withdrawal. Such individuals typically use relatively large doses of benzodiazepines intermittently, and therefore many of these patients do not develop physical dependence on benzodiazepines, unlike the first category of patients described previously, for whom physical dependence is common.

TREATMENT Rx

The treatment of people who are abusing benzodiazepines depends to some extent on the pattern of abuse. For individuals who have an anxiety disorder and have been misusing a legitimately prescribed medication, a common approach would be to taper the benzodiazepine and to institute a different type of treatment, such as an antidepressant along with cognitive-behavioral therapy. Tapering a benzodiazepine that a person has been taking for an extended period of time (sometimes many years) often requires a slow process, with careful monitoring of withdrawal symptoms (anxiety, agitation, insomnia, tachycardia, palpitations). Because benzodiazepine withdrawal, like alcohol withdrawal, can precipitate a seizure, gradual withdrawal is preferred. Most patients tolerate a benzodiazepine dose reduction initially with relatively little difficulty. However, as with most drug withdrawal regimens, people experience their greatest difficulty toward the end of the taper. One reason for this is that the percent dose reduction at the low end of a taper regimen continues to increase over time; a reduction from 2 mg to 1.5 mg of clonazepam, for instance, is a 25% reduction, whereas the same half-milligram dose reduction from 1 mg to 0.5 mg represents a 50% drop.

For patients who are abusing benzodiazepines as part of a pattern of multiple substance use, medical detoxification from the benzodiazepine itself will often not be necessary; for this population, psychosocial approaches that advocate abstinence from all substances of abuse, in conjunction with appropriate pharmacotherapy as needed (e.g., in the case of opioid dependence), is the preferred approach. It is important to note, however, that some deaths have been reported in France and elsewhere as a result of combinations of buprenorphine and benzodiazepines, usually used parenterally. Thus, physicians who are treating patients who are abusing both opioids and benzodiazepines need to be mindful of this issue when considering the use of buprenorphine.

Marijuana

Marijuana, which refers to the dried leaves and flowers of the plant *Cannabis sativa,* has been used for its psychoactive and medicinal properties for centuries. The major psychoactive substance in marijuana is δ-9-tetrahydrocannabinol (THC); the concentration of THC has increased from 1 to 3% in 1970 to nearly 8% in 2005; more potent varieties such as sinsemilla may contain nearly twice as much THC.

EPIDEMIOLOGY

Marijuana is the most commonly used illicit drug worldwide; it is estimated that approximately 160 million people have used marijuana. More than 16 million Americans state that they have used marijuana in the past month, with 104 million people in the United States having used marijuana during their lifetime.

PATHOBIOLOGY

Marijuana and other cannabinoids such as hashish (dried cannabis resin) exert their effects by binding to the cannabinoid receptors, of which two are currently known. Binding to the CB1 receptor, which is located primarily in the brain, appears to be responsible for the psychoactive effects of THC, whereas the CB2 receptor may be associated with immune system responses.

CLINICAL MANIFESTATIONS

When marijuana is smoked, its psychoactive effects occur almost immediately, with peak intensity approximately 30 minutes later; effects tend to disappear within 3 hours. Oral administration of marijuana leads to a delayed onset of action, but the effects of the drug persist for a longer period of time. Because THC is highly soluble in lipids, it can be stored in fat depots of regular users for several weeks, sometimes longer, with resultant positive urine tests for THC. Physiologic effects of marijuana intoxication include increased heart rate and conjunctival injection. Psychological effects include a sense of euphoria and well-being, friendliness, increased appetite, a distorted sense of time, impaired short-term memory, and sometimes a feeling of having achieved special insights. Cannabis has the capacity to cause tolerance in regular users, and some regular heavy users experience withdrawal symptoms on cessation of use, including irritability, difficulty sleeping, and anxiety.

TREATMENT Rx

The most common acute adverse event that occurs in marijuana smokers is a sense of acute panic, most common in inexperienced smokers, when the user's level of intoxication is greater than expected and the individual feels out of control. This can be best managed with reassurance that the effects will go away as the drug wears off. Recent evidence has shown that cannabis use, particularly during adolescence, may increase the likelihood of development of a psychotic disorder such as schizophrenia later in life.

Compared with alcohol, opioids, and stimulants, it is relatively uncommon for people to seek treatment of cannabis dependence itself. However, that situation has gradually changed in recent years, and an increasing number of people have sought treatment because of difficulty stopping marijuana use. There are no medications approved by the FDA for the treatment of cannabis dependence. Psychosocial approaches similar to the treatment of other substance use disorders are currently the treatment of choice.

Hallucinogens

Hallucinogens are a group of plant-based and synthetic drugs that lead to (primarily visual) perceptual alterations such as illusions and hallucinations, along with an alteration in the experience of external stimuli; ordinary events can appear quite profound to people while they are under the influence of these agents. The most common hallucinogens are lysergic acid diethylamide (LSD), mescaline, and psilocybin. Methylene dioxymethamphetamine (MDMA), also known as *ecstasy,* has both mild stimulant and potentially hallucinogenic properties and is thus sometimes categorized with the hallucinogens and sometimes as a stimulant.

EPIDEMIOLOGY

Approximately 1.3 million people in the United States report having used a hallucinogen in the previous month; approximately 37 million people have used these drugs during their lifetime. LSD is the most commonly used hallucinogen, with 24 million lifetime users in the United States; approximately 60% of that number have used MDMA.

PATHOBIOLOGY

LSD is thought to exert its action through serotonin agonist activity, particularly at the 5-HT_{2A} receptor. Other neurotransmitters may be involved in hallucinogenic activity as well. Hallucinogens can produce tolerance in a matter of days, but they do not produce physical dependence.

CLINICAL MANIFESTATIONS

In addition to their effects on perception and behavior, hallucinogens can produce sympathomimetic effects such as tachycardia, increased blood pressure and body temperature, and pupillary dilatation. Hyperreflexia and muscle weakness can also be seen. The most commonly seen medical consequence of hallucinogen use is hyperthermia, which can occur most commonly in users of MDMA.

The most common acute psychological adverse event, similar to marijuana, is a feeling of panic over the sense of loss of control that a person may feel as a result of intoxication; as is the case with marijuana, this is most likely to occur in inexperienced users. Some hallucinogen users will develop psychotic symptoms that fail to remit after the drug has worn off. Some hallucinogen use can also lead to longer-term perceptual difficulties. When these occur, a spontaneous return of very brief hallucinogen-induced symptoms long after the drug has worn off is known as a *flashback.* People who have perceptual difficulties that are much more pervasive may be said to have *hallucinogen persisting perception disorder,* which can at times be quite disabling.

TREATMENT Rx

Symptomatic treatment is focused on the specific adverse medical and psychiatric sequelae described previously. If a psychotic episode that occurs after use of a hallucinogen persisted over time, it would be treated like any other psychotic disorder. There is no specific treatment for abuse of or dependence on hallucinogens per se, and it is very uncommon for people to seek treatment specifically because they want to stop using hallucinogens.

Phencyclidine

Phencyclidine (PCP) was originally developed as a human general anesthetic, but its use for that purpose was stopped in the 1960s because it frequently led to psychosis and hallucinations in the postoperative period. Approximately 120,000 individuals report that they used PCP during 2009, which represents more than a 40% decline from 5 years previous to that. Low doses of PCP can lead to symptoms that resemble alcohol intoxication, with slurred speech, ataxia, and a subjective feeling sometimes described as "feeling dead." PCP intoxication typically is accompanied by increased muscle tone, hyperreflexia, nystagmus, and ataxia.

When taken in high doses, PCP can have serious medical and psychiatric consequences. High-dose users may experience psychosis, catatonia, and extremely violent behavior. Medical sequelae of PCP intoxication can include muscle rigidity, seizures, hyperthermia, coma, and occasionally death.

Anabolic-Androgenic Steroids

Anabolic-androgenic steroids differ from other drugs described in this chapter because the motivation for use is typically related to the drug's physical rather than behavioral effects. Anabolic-androgenic steroids such as testosterone and its synthetic analogues have traditionally been used primarily to enhance strength and thus athletic performance, although in recent years, an increasing number of people have used these drugs primarily in an attempt to improve their physical appearance. Anabolic-androgenic steroids can have a legitimate medical purpose; they have most commonly been used to treat testosterone deficiency in men and more recently have been used to treat wasting syndromes in patients with AIDS.

Abuse of anabolic-androgenic steroids can cause a number of medical and psychiatric problems, including hypertension, elevated low-density lipoprotein cholesterol, cardiomyopathy, hepatotoxicity, acne, feminization (gynecomastia and reduced testicular size) in men, and masculinization (hirsutism, reduction in breast tissue, deeper voice) in women. Behavioral effects include aggressiveness (sometimes leading to violence) and an increased prevalence of mood disorders. There is no specific treatment to help people abusing anabolic steroids to stop. Rather, behavioral treatment approaches that are commonly used to treat other substance use disorders should be employed with this population.

CONCLUSION AND FUTURE DIRECTIONS

The ever-changing epidemiology of drug abuse means that the next decade will likely present new challenges as new drugs of abuse become increasingly popular. Recent research has focused on developing and testing effective pharmacologic and behavioral treatments for drug abuse and dependence. Screening for these disorders in general medical practice and combining office-based interventions with referrals to specialty drug abuse treatment as indicated can lead to successful outcomes for many of these patients.

IMMUNOSUPPRESSING DRUGS INCLUDING CORTICOSTEROIDS

GRANT W. CANNON

IMMUNOSUPPRESSIVE DRUGS

The immune response is an essential host defense mechanism to control and fight infection. The ability to suppress immune reactions is a critical component in autoimmune disease treatment and transplantation management. During autoimmune diseases, the basic immune physiology is altered, and one or more components of this process do not function properly. Current challenges related to the selection, dosing, monitoring, and development of immunosuppressive drugs involve identifying the component of the immune system to be altered by the immunosuppressive therapy while maintaining a competent immune response to fight infection and perform other important immunoregulatory functions. After organ transplantation, most patients have an immune response to reject the implanted organ. Thus, immunosuppression during transplantation management involves the suppression of normal immune reactions rather than a pathologic process, as in the treatment of autoimmune disease. Suppression of natural host immune responses inevitably affects the ability of these protective mechanisms to fight infection. The general principles for selecting immunosuppressive therapy in transplantation patients involve specific monitoring for organ rejection and the selection of immunosuppressive therapy proportionate to the degree of rejection or to maintain tolerance of the implanted organ. Selection of the most effective therapy requires an individualized treatment program. These decisions require an understanding of the underlying pathophysiologic process, prognosis, and potential adverse events associated with the agents selected.

This chapter describes the mechanism of action—including the components of the immune response affected by the therapy—indications, and adverse events associated with commonly used immunosuppressive agents in autoimmune diseases and transplantation. Although each of these agents is discussed individually, these drugs are frequently used in combination to take advantage of their complementary effects. An understanding of the principles and adverse events associated with immunosuppressive therapy is important for all physicians as the use of these drugs becomes more widespread; however, the initiation and management of immunosuppressive therapy, particularly in patients with organ transplants and severe autoimmune diseases, should generally be limited to specialists with specific training in its use.

Corticosteroids

Historically, the initial enthusiasm related to the marked clinical benefit of corticosteroids in the treatment of rheumatoid arthritis was dampened by the significant adverse effects that developed after prolonged use. As opposed to allergic and idiosyncratic reactions to medications, the majority of adverse effects related to corticosteroid therapy are a direct consequence of the physiologic effects of the drug. This observation sparked a determined effort to understand the mechanisms of action of corticosteroids at physiologic levels and therapeutic doses. The objectives of these investigations have been to modify the naturally occurring hormones to exploit their clinical benefits while avoiding the associated adverse effects.

Mechanism of Action

Corticosteroids affect multiple physiologic functions at the molecular, cellular, and organ levels. The final result of corticosteroid treatment represents the composite effects of the drug on these multiple functions, which vary with the particular agent, dose, route, and duration of treatment (Table 34-1).

Molecular Action

Genomic Effects

Corticosteroids are lipophilic and rapidly cross cell membranes into the cytosol, where they bind to the glucocorticoid receptor. The complex of glucocorticoid and its receptor then enters the nucleus and affects gene transcription by binding to glucocorticoid response elements. The complex may either stimulate or suppress gene transcription and subsequent protein production. This mechanism may have an impact on the function of 1% of all genes and suppresses the production of cytokines and other important inflammatory proteins. In addition to binding to glucocorticoid response elements, the glucocorticoid–glucocorticoid receptor complex suppresses signal transduction pathways such as transcription factor activator protein-1, nuclear factor-κB, and nuclear factor of activator of T cells. Corticosteroids may also affect post-transcription and post-translation steps of protein synthesis. The anti-inflammatory actions of corticosteroids may be related to

TABLE 34-1 MECHANISM OF ACTION OF IMMUNOSUPPRESSIVE AGENTS

CORTICOSTEROIDS
Binding to cytosol glucocorticoid receptor results in suppression of pro-inflammatory cytokines (genomic effects)
Inhibition of arachidonic acid release and binding to surface receptor (nongenomic effects)
Results of corticosteroid actions:
Leukocyte numbers
Increase in circulating neutrophils
Decrease in circulating lymphocytes, monocytes, eosinophils, and basophils
Leukocyte function
Decreased trafficking of neutrophils
Decrease in leukocytes' cellular immune functions and immunoglobulin production
Cytokines
Decrease in pro-inflammatory cytokines: IL-1, IL-2, IL-6, and tumor necrosis factor-α
Increase in anti-inflammatory cytokines: IL-4, IL-10, and IL-13
Decreased production of prostaglandins and leukotrienes
PURINE PATHWAY INHIBITORS
Azathioprine: inhibition of DNA synthesis and purine synthesis
Mycophenolate mofetil: inhibition of purine synthesis
PYRIMIDINE PATHWAY INHIBITORS
Leflunomide: inhibition of pyrimidine synthesis by inhibiting dihydroorotate dehydrogenase
IMMUNOPHILIN-BINDING AGENTS
Calcineurin inhibition
Cyclosporine: binds with cyclophilin to inhibit calcineurin, resulting in decreased T-cell activation
Tacrolimus: binds with FKBP12 to inhibit calcineurin, resulting in decreased T-cell activation
Mammalian target of rapamycin (mTOR) inhibition
Sirolimus: binds to FKBP12 to inhibit mTOR, resulting in decreased T-cell activation
ALKYLATING AGENTS
Cyclophosphamide: alkylation of nucleic acids with cytotoxic action

FKBP12 = 12-kD FK-binding protein; IL = interleukin.

their action on the nuclear factor-κB and activator protein-1 pathways; the adverse events produced are related more to the activation or suppression of gene transcription.

Nongenomic Effects

The genomic effects of corticosteroids require the diffusion of the drug into the cell, binding to the receptor, entry into the nucleus, and alteration of transcription. The ultimate effect on protein synthesis is not immediate, and it generally takes at least 30 minutes before any response is seen. The observation that some actions of corticosteroids are seen immediately has directed a search for nongenomic effects of these drugs. The glucocorticoid–glucocorticoid receptor complex can inhibit arachidonic acid release. In addition to the cytosol glucocorticoid receptor, a membrane-bound receptor may be present that mediates nongenomic functions.

Systemic Effects

Impact on Leukocytes

Corticosteroids affect the activation, production, circulation, function, and survival of leukocytes. Whereas these impacts appear to be modulated principally by the genomic effects of corticosteroids on cytokines, corticosteroids act on adhesion molecules and other mechanisms as well. The effects are on neutrophils, monocytes, macrophages, lymphocytes, eosinophils, and basophils. With corticosteroid therapy, neutrophils increase in the peripheral circulation, primarily because of demargination; in contrast, there is a decrease in monocytes, lymphocytes, eosinophils, and basophils. Although the number of circulating neutrophils may increase, trafficking appears to be impaired. The impact on T cells is more pronounced than the effects on B cells, with the induction of apoptosis particularly in immature and activated T cells. Although the function of B cells and neutrophils is not affected as strongly as that of T cells, prolonged use of high-dose corticosteroids can lead to suppression of antibody production.

Changes in Inflammatory Mediators

Corticosteroids result in a decrease in multiple pro-inflammatory cytokines and interleukins (ILs), including IL-1, IL-2, IL-6, and tumor necrosis factor-α, at the same time that there is an increase in anti-inflammatory cytokines such as IL-4, IL-10, and IL-13. Corticosteroids have been associated with a reduction in the production of prostaglandins, leukotrienes, and other arachidonic acid metabolites, probably related to the reduced production of cyclooxygenase 2 and phospholipase A_2–related pro-inflammatory compounds (Chapter 36).

TREATMENT Rx

Specific Issues with Corticosteroid Therapy

Multiple corticosteroid compounds and preparations are available (Table 34-2). These compounds have differences in potency, half-life, and sodium-retaining properties. In many conditions, the local administration of corticosteroids provides clinical benefit without the systemic toxicity associated with oral therapy. Local therapies include topical, ophthalmic, inhaled, and local injection, such as soft tissue and intra-articular injections. Although the potential for adverse events is generally reduced with local therapy, local toxicities as well as systemic effects can develop if large doses of topical corticosteroids are used.

Whereas most conditions can be treated with local or oral corticosteroids, intravenous administration can provide pulse doses if desired. Intravenous therapy can also be used when the patient cannot take oral medication or the absorption of oral agents is impaired. Pulse therapy generally consists of high-dose intravenous treatment that is often administered as divided doses over 3 to 5 days. High-dose pulse therapy has been advocated in acute organ transplantation rejection, severe systemic lupus erythematosus (SLE), aggressive vasculitis, and other acute and severe autoimmune disorders. The use of high-dose corticosteroid pulse therapy has been associated with the development of sudden cardiac arrhythmias and sudden death. However, many of these patients had serious concurrent diseases that could have been partly responsible for electrolyte abnormalities and other associated morbidities contributing to these complications. Because of this possible association, close monitoring of patients receiving high-dose corticosteroid pulse therapy is warranted.

Indications

Corticosteroids are employed in a wide range of autoimmune disorders and transplantation procedures. A listing of each indication for which corticosteroids have been used and proved effective is beyond the scope of this chapter, but indications range from multiple rheumatologic disorders and many other inflammatory conditions to transplantation. For example, the demonstration that inflammation plays a significant role in reactive airway disease has dramatically increased the use of systemic and inhaled corticosteroids in asthma and chronic obstructive pulmonary disorders. The challenge is to determine the appropriate dose, route, and duration of therapy. For severe autoimmune disorders, high doses of corticosteroids are indicated. In many cases, oral prednisone, 60 to 80 mg/day as single or divided doses, can be employed. If patients cannot take oral medication or higher doses of corticosteroids are indicated, they can be administered intravenously. Comparative data on the most appropriate doses and routes of administration are generally not available. Clinical judgment and empirical literature form the basis of these treatment regimens.

Adverse Effects

With most medications, adverse events are the result of allergic and idiosyncratic reactions. The adverse events associated with corticosteroids, however, are generally caused by the drug's physiologic action. Investigations are ongoing to determine whether separate mechanisms might account for the therapeutic benefits of corticosteroids, whereas other pathways are involved in the adverse events related to these drugs. Currently available forms of corticosteroids do not allow the separation of adverse events from therapeutic effects. For example, the increase in infection associated with corticosteroids is a result of the drug's impact on leukocyte function and antibody production; it is not an allergic reaction. The prevalence and severity of these adverse effects increase in proportion to the dose and duration of therapy. The key to reducing adverse events is to use the lowest dose needed for the shortest possible duration. Data also suggest that intermittent and every-other-day dosing may be associated with less toxicity than daily or divided daily doses.

Despite these limitations, corticosteroids are the only viable treatment option in many conditions, and efforts must be made to prevent, detect the development of, and monitor these adverse events. In most situations, education of the patient coupled with vigilant surveillance can detect these adverse events and often reduce their serious impact.

The following discussion is not a comprehensive list of all reported adverse events associated with corticosteroids. Infection, osteoporosis, metabolic abnormalities, and cardiovascular effects are highlighted because specific interventions can have an impact on these problems through proper education of the patient, monitoring, or prophylactic therapy.

Infection

Infections are increased in patients taking corticosteroids, particularly bacterial, fungal, and mycobacterial infections. These opportunistic infections are seen much less frequently in healthy individuals with normal immune function. The increased incidence and general severity of these infections are complicated by the anti-inflammatory actions of corticosteroids, which can mask many of the cardinal signs of infection such as fever, inflammation, and local discomfort. Patients taking corticosteroids should be alerted to the possibility of these "subclinical" infections, and the provider must be vigilant in investigating signs and symptoms that might be less concerning in patients not taking corticosteroids. Management of infections in patients receiving corticosteroids requires close monitoring. Appropriate diagnostic procedures, antimicrobial therapy, and supportive measures are key to the successful management of infections in immunocompromised hosts. Patients with adrenal suppression may require "stress doses" of corticosteroids during the initial treatment. However, when a reduction in corticosteroid dose is possible, this may help restore the host immune response to the infection, particularly with chronic infections.

Preventive measures to reduce infections include proper immunizations. For example, in a patient being evaluated for future transplantation, immunizations should be given before the immunosuppressive therapy, if possible. In many cases, however, a delay of immunosuppressive therapy is not possible to allow immunizations to be updated. In patients receiving chronic immunosuppressive therapy, routine immunizations should be offered when the disease is stable. Prophylactic antibiotics are generally not recommended to prevent infections in patients receiving corticosteroid therapy. However, two notable exceptions are the use of antituberculosis therapy in purified protein derivative (PPD)–positive patients and trimethoprim-sulfamethoxazole therapy in patients receiving high-dose corticosteroid therapy for *Pneumocystis jirovecii* (previously *Pneumocystis carinii*) prophylaxis.

TABLE 34-2 GLUCOCORTICOID PREPARATIONS

	ANTI-INFLAMMATORY POTENCY	EQUIVALENT DOSE (MG)	SODIUM-RETAINING POTENCY	PLASMA HALF-LIFE (MIN)	BIOLOGIC HALF-LIFE (HR)
Hydrocortisone	1	20	2+	90	8-12
Cortisone	0.8	25	2+	30	8-12
Prednisone	4	5	1+	60	12-36
Prednisolone	4	5	1+	200	12-36
Methylprednisolone	5	4	0	180	12-36
Triamcinolone	5	4	0	300	12-36

Osteoporosis

Bone loss associated with corticosteroids affects multiple sites and has a greater impact on trabecular bone than cortical bone. Common sites of involvement are the spine and femur; associated fracture rates may be as high as 20%, depending on the dose and duration of therapy. On initiation of long-term corticosteroid therapy, all patients should be evaluated for osteoporosis prophylactic therapy (Chapter 251). Unless it is contraindicated, patients should be receiving adequate calcium and vitamin D through diet or supplements. In many patients, bisphosphonates provide significant protection. Postmenopausal women may be evaluated for potential estrogen replacement therapy, which may be helpful if the benefits of therapy with corticosteroids outweigh the risks for cardiovascular disease and malignancy. If osteoporosis develops in a patient receiving corticosteroids, efforts should be made to discontinue therapy or reduce the dose. Agents used for the treatment of osteoporosis should also be administered (Chapter 251). Effective therapies include bisphosphonates and anabolic agents such as parathyroid hormone preparations. These agents are generally used in association with calcium and vitamin D supplementation. An algorithm for the prevention and treatment of glucocorticoid-induced osteoporosis is provided in Figure 34-1.

Metabolic Effects

The metabolic effects of corticosteroids may influence glucose metabolism, with results ranging from mild glucose intolerance to frank diabetes. Patients beginning corticosteroid therapy should be monitored for glucose intolerance and treated if significant hyperglycemia develops. The management of patients with existing diabetes is particularly challenging during corticosteroid therapy; they require close monitoring and adjustments to their diabetes management programs.

Exogenous corticosteroids suppress the hypothalamic-pituitary-adrenal (HPA) axis (Chapters 230 and 234). The likelihood of adrenal suppression increases with the dose and duration of therapy. HPA axis suppression should be considered in patients receiving doses of 20 mg/day or more for 3 weeks or longer, although suppression can occur with lower doses. Formal evaluations can be performed to test the integrity of the HPA axis, but in most cases, a scheduled tapering of corticosteroid dose over several weeks allows the return of HPA axis function without signs of adrenal insufficiency. The ideal rate for the tapering of corticosteroids has not been evaluated by clinical trials. The rate of reduction in corticosteroid dose is often limited more by the relapse of disease activity than by the development of adrenal insufficiency. In general, a rapid reduction in dose (about 10 mg prednisone-equivalent/day), as tolerated by the patient's clinical disease, can be undertaken until a dose reflecting the normal physiologic production of cortisol is achieved. After this point, reductions of 1 to 2.5 mg/day every 1 to 2 weeks are generally well tolerated and can be accomplished by decreasing the dose of alternate-day treatment over 6 to 8 weeks. However, with an acute medical illness, patients who received corticosteroid doses in the past sufficient to cause HPA suppression should receive stress doses of steroids for up to 1 year after steroid treatment. Other metabolic complications of corticosteroid treatment include weight gain with truncal obesity; electrolyte abnormalities, including hypokalemia; and fluid retention.

Cardiovascular Effects

Corticosteroids may induce or exacerbate cardiovascular risk factors, including hypertension, hyperlipidemia, and diabetes. Multiple mechanisms have been proposed for these effects, but the end result is that patients taking corticosteroids have an increased prevalence of atherosclerotic diseases and their associated complications. This problem is complicated by the recent observation that many patients with inflammatory conditions, including rheumatoid arthritis and SLE, may have an increased risk for cardiovascular disease above that predicted by traditional risk factors. These observations emphasize the need to monitor corticosteroid-treated patients closely for cardiovascular risk factors (Chapter 51) and to treat detected abnormalities aggressively.

Other Adverse Effects

Many other adverse events have been reported with corticosteroid therapy and are listed in Table 34-3. Osteonecrosis (avascular necrosis) is common during corticosteroid therapy and often involves the femoral head. Peptic ulcer disease is increased independent of concurrent nonsteroidal anti-inflammatory therapy. Cataracts and a variety of dermatologic abnormalities are more common. Muscle weakness or steroid myopathy, alteration of mood and behavior, and psychosis may develop. This broad spectrum of clinical complications requires the prescriber of corticosteroids to be aware of and alert to the development of these adverse events.

Purine Inhibition

Purines are critical components of nucleic acids and are particularly important in proliferating cells as part of cell growth and division. The inhibition of purines by competitive inhibitors (azathioprine and 6-mercaptopurine) and the blocking of critical enzymes (mycophenolate mofetil) in the purine pathway are effective methods of immunosuppression.

Azathioprine and 6-Mercaptopurine

Mechanism of Action

Azathioprine is an inactive compound that is metabolized to the active compound 6-mercaptopurine (6-MP). The exact mechanisms of action of 6-MP and its metabolites have not been fully established. At high doses, 6-MP may be incorporated into RNA and DNA, resulting in a cytotoxic effect; however, this effect is probably not the drug's major action at the usual doses employed. Most likely through the feedback inhibition of de novo purine synthesis, 6-MP and its metabolites may reduce cell proliferation and thus produce immunosuppression. Genetically controlled differences in the activity of enzymes involved in the metabolism of 6-MP have been identified. The enzyme thiopurine *S*-methyltransferase is responsible for the metabolism of 6-MP to the metabolite methyl-6-MP. A rare homozygous (0.3%) and heterozygous (10%) defect in thiopurine *S*-methyltransferase is associated with increased toxicity, with severe hematologic toxicity in homozygous patients.

The drug is eventually metabolized by xanthine oxidase. Because xanthine oxidase is inhibited by allopurinol, the concurrent use of allopurinol and azathioprine or 6-MP can result in a significant reduction in the metabolism of the active compounds and a significant increase in drug toxicity. For this reason, the combination of allopurinol and azathioprine should be avoided.

Indications

Azathioprine is approved by the Food and Drug Administration (FDA) for the prevention of renal transplant rejection and for the treatment of rheumatoid arthritis. Clinical trials and reports suggest that azathioprine also has efficacy in other types of organ transplantation and autoimmune diseases. Azathioprine has been particularly effective as an adjunct to corticosteroid

TABLE 34-3 MAJOR ADVERSE EVENTS ASSOCIATED WITH IMMUNOSUPPRESSIVE THERAPIES*

CORTICOSTEROIDS
Serious and opportunistic infections
Osteoporosis
Metabolic disorders: hyperglycemia, adrenal suppression, hyperlipidemia, electrolyte abnormalities, fluid retention, hypertension, truncal obesity
Cardiovascular
Miscellaneous: osteonecrosis, peptic ulcer disease, cataracts, dermatologic abnormalities, steroid myopathy, psychosis, growth retardation, altered mood and behavior
AZATHIOPRINE
Serious and opportunistic infections
Hematologic abnormalities: leukopenia, thrombocytopenia, anemia
Gastrointestinal: nausea, vomiting, rare hepatitis
Reproductive: pregnancy class D
Miscellaneous: pancreatitis, interstitial pneumonitis, rashes
MYCOPHENOLATE MOFETIL
Serious and opportunistic infections
Leukopenia
Gastrointestinal: diarrhea, nausea, dyspepsia, elevated transaminases
Reproductive: pregnancy class C
CYCLOSPORINE
Serious and opportunistic infections
Renal disease and hypertension
Potential for increased malignant neoplasms
Reproductive: pregnancy class C
Miscellaneous: hirsutism, gingival hyperplasia, hyperuricemia, electrolyte abnormalities
TACROLIMUS
Serious and opportunistic infections
Renal disease and hypertension (perhaps lower than with cyclosporine)
Potential for increased malignant neoplasms
Post-transplantation diabetes mellitus
Neurotoxicity: tremor, headaches, motor function abnormalities, mental status alteration, sensory changes
Reproductive: pregnancy class C
Miscellaneous: hirsutism, gingival hyperplasia, myocardial hypertrophy
SIROLIMUS
Serious and opportunistic infections
Renal disease and hypertension
Potential for increased malignant neoplasms
Reproductive: pregnancy class C
Miscellaneous: hyperlipidemia, pneumonitis, interstitial lung disease
CYCLOPHOSPHAMIDE
Serious and opportunistic infections
Increased incidence of malignant neoplasms
Hematologic toxicity: leukopenia, thrombocytopenia, anemia
Reproductive: pregnancy class D, premature ovarian failure, oligospermia, fetal abnormalities
Urologic: hemorrhagic cystitis, bladder cancer
Miscellaneous: nausea, vomiting, diarrhea, pulmonary fibrosis

*This list highlights the most serious and common adverse events but does not include all reported adverse events with these agents.

therapy, allowing a reduction in corticosteroid dose and avoiding the associated adverse events.

Adverse Effects

Serious infection has been reported during treatment with azathioprine, similar to that seen with other immunosuppressive drugs. Opportunistic infections are a particular concern. Hematologic abnormalities include leukopenia, thrombocytopenia, and anemia. A complete blood count (CBC) is recommended on a regular basis, with greater frequency at the initiation of therapy. Current guidelines recommend a CBC weekly during the first month of azathioprine therapy, every 2 weeks during the second and third months, and monthly thereafter. Genotyping of the enzyme thiopurine *S*-methyltransferase may identify subjects at the highest risk for hematologic toxicity, but it does not substitute for monitoring of the CBC. Gastrointestinal toxicity is usually minor, but patients may have significant symptomatic complaints of nausea, vomiting, diarrhea, and epigastric pain; these are often self limited and reversible. Severe hepatic toxicity has been rarely reported, leading to a recommendation for regular monitoring of serum transaminases, alkaline phosphatase, and bilirubin, particularly during the first 6 months of therapy. Rare complications of azathioprine treatment include fever, arthralgia, rash, pancreatitis, and interstitial pneumonitis.

Azathioprine use in pregnancy is classified as category D and has been associated with fetal abnormalities in animals. The use of azathioprine should be avoided, if possible, in pregnant women and nursing mothers, although patients with organ transplants and autoimmune disease have had successful pregnancies while receiving azathioprine.

The association between azathioprine treatment and the development of malignant neoplasms is controversial. In most clinical situations, azathioprine is used in conditions and in combination or temporal sequence with other drugs that are associated with the development of malignancies. For example, patients with systemic vasculitis or SLE may initially be treated with cyclophosphamide and then with azathioprine. An increase in malignant neoplasms in this population could be related to azathioprine treatment, but the prior cyclophosphamide therapy may be a greater risk factor. In addition, patients with solid organ transplantation, another circumstance in which azathioprine is frequently used, appear to have a higher rate of malignant neoplasms unrelated to the use of immunosuppressive drugs. Extensive efforts to identify an independent increased risk for malignant neoplasms with azathioprine have not produced consistent results. These results suggest that the risk for malignant transformation with azathioprine is very low, if it exists at all.

Azathioprine is an important and effective therapy in organ transplantation and autoimmune disease. It is often used in combination with other agents and as a corticosteroid-sparing drug. Surveillance for infection and monitoring for hematologic toxicity are important. Concurrent treatment with allopurinol should be avoided to prevent serious toxicity from an interaction of the two drugs.

Mycophenolate Mofetil

Mechanism of Action

Mycophenolate mofetil is a prodrug that is converted in vivo to the active compound mycophenolic acid. Mycophenolic acid acts through inhibition of the enzyme inosine monophosphate dehydrogenase, resulting in an increase in 6-thionosinic acid, which is normally metabolized by this enzyme. The accumulation of 6-thionosinic acid acts via a negative feedback loop to suppress the de novo synthesis of purines and associated DNA production. Although it is not a cytotoxic agent, the actions of mycophenolic acid are most pronounced on proliferating cells, such as lymphocytes, reducing cell division and associated functions of these critical cells in the immune response.

Indications

Mycophenolate mofetil is approved by the FDA for the prevention of allograft rejection in renal, hepatic, and cardiac transplantation. In addition to these approved indications, mycophenolate mofetil has been evaluated in SLE; its principal use is in patients with lupus nephritis, although the drug has been used for other manifestations. Current studies are seeking to determine whether this agent can replace cytotoxic agents, such as cyclophosphamide, in the treatment of SLE, particularly as initial and maintenance therapy for lupus nephritis. Limited use has been reported in other autoimmune diseases such as rheumatoid arthritis, vasculitis, and polymyositis.

Adverse Effects and Monitoring

Common adverse events with mycophenolate mofetil include hematologic and gastrointestinal complications. Leukopenia is reported in 20 to 35% of patients receiving this drug for organ transplantation; however, severe neutropenia is seen in only 2 to 3% of subjects. Patients receiving mycophenolate mofetil have a higher susceptibility to infections, including opportunistic infections, similar to that seen with other immunosuppressive agents. Diarrhea, nausea, and dyspepsia are frequent. Abnormalities of liver enzymes are commonly noted and appear to be dose dependent. Rare complications include pulmonary fibrosis and malignant neoplasms. Mycophenolate mofetil is classified as category C by the FDA for use in pregnant women. Although the agent should be avoided in patients who are pregnant or not practicing adequate contraception, this drug appears to have less impact on the reproductive system than does cyclophosphamide. Patients with SLE who are concerned about cyclophosphamide's potential

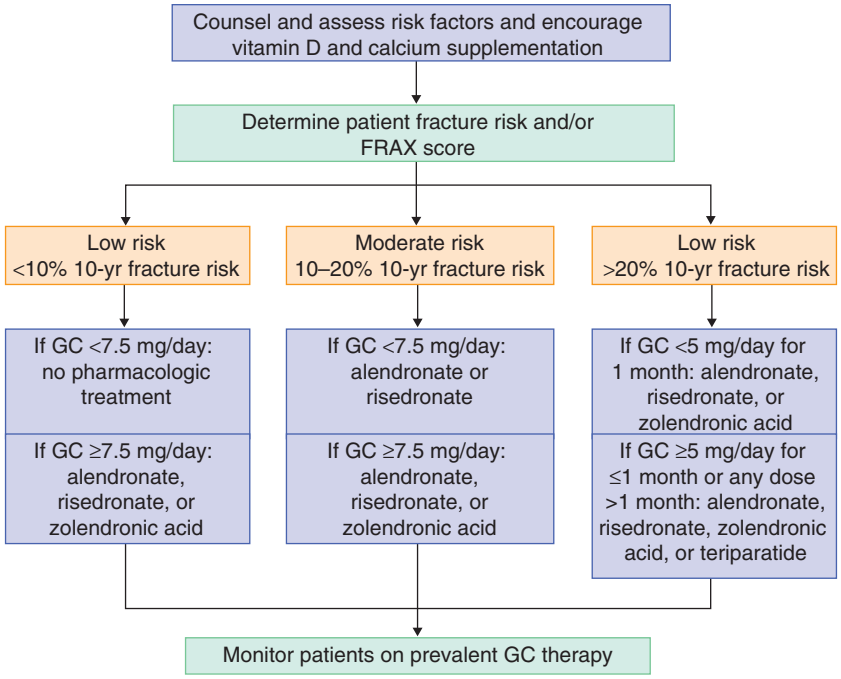

FIGURE 34-1. Algorithm for the prevention of steroid-induced osteoporosis on initiation of glucocorticoid (GC) therapy. FRAX = World Health Organization Fracture Assessment Tool. (Modified from American College of Rheumatology 2010 recommendations for the prevention and treatment of glucocorticoid-induced osteoporosis. *Arthritis Rheum.* 2010;62:1515-1526.)

severe impact on reproductive organs may elect to use mycophenolate mofetil instead.

Monitoring of patients receiving mycophenolate mofetil should include a monthly CBC and hepatic enzyme activities. Monitoring for gastrointestinal and infectious complications should be conducted during regular clinical follow-up.

Mycophenolate mofetil is an important and effective agent in the management of transplant patients. Ongoing studies are evaluating the role of this drug in other autoimmune diseases. It is hoped that mycophenolate mofetil can provide effective therapy for rheumatic and autoimmune disorders with less toxicity than that associated with currently available agents. It has particular potential for use in lupus nephritis.

Immunophilin-Binding Agents

The development of immunophilin inhibitors has significantly advanced organ transplantation. Each of these drugs—cyclosporine, tacrolimus (also known as FK506), and sirolimus (also known as rapamycin)—has significant immunosuppressive activity on T-cell–mediated functions. Although the mechanism of action for each drug differs, they all bind to a cytosolic protein. This binding results in a decrease in T-cell cytokine production and T-cell proliferation. These separate sites of action allow these agents to be used in combination in transplantation management. In addition, because of these differences in action and binding, each drug has a unique adverse event profile.

Cyclosporine

Mechanism of Action

Cyclosporine acts by binding to the cytosolic protein cyclophilin to form a cyclosporine-cyclophilin complex. The cyclosporine-cyclophilin complex inhibits the enzyme calcineurin, which is involved in multiple T-cell functions and is of particular importance in enhancing the transcription of genes for pro-inflammatory cytokines. The use of cyclosporine inhibits the production of IL-2, resulting in a decrease in T-cell activation. Cyclosporine also inhibits the production of other cytokines, including IL-3, IL-4, granulocyte-macrophage colony-simulating factor, tumor necrosis factor-α, and interferon-γ. The overall impact of these actions is to reduce immune function and inflammation.

Indications

The use of cyclosporine and other calcineurin inhibitors has revolutionized treatment after solid organ transplantation. The specific FDA-approved indications include renal, liver, and heart transplantation. Most often the drug is used in conjunction with other immunosuppressive agents, including corticosteroids and azathioprine. The critical clinical challenge is to balance the potent immunosuppressive effects of the drug against its adverse effects, with particular attention to the avoidance of infectious complications and monitoring for hypertension and renal toxicity. Because of these critical issues, prescription of this drug is limited to physicians experienced in the use of immunosuppressive agents.

Oral cyclosporine is also approved for the treatment of rheumatoid arthritis as a disease-modifying antirheumatic drug (DMARD), either alone or in combination with methotrexate. Although it is effective in the treatment of rheumatoid arthritis and other rheumatic diseases, cyclosporine does not have substantially greater efficacy than the other DMARDs. Cyclosporine is also approved for the treatment of psoriasis. Because of its significant adverse event profile, cyclosporine is generally reserved for patients with autoimmune diseases who have failed therapy with more traditional and less toxic agents.

Topical cyclosporine is effective and is approved to increase tear production, presumed to be suppressed secondary to inflammation, in patients with keratoconjunctivitis sicca syndrome. Topical treatment is associated with a much lower frequency of adverse drug events than is systemic cyclosporine therapy.

Adverse Effects

Close monitoring is required during cyclosporine therapy. Blood levels can be measured, which is useful to ensure that the drug remains within the therapeutic range and below levels associated with increased toxicity. Because many potential drug and food interactions can either raise or lower cyclosporine levels, such as increased levels seen with the ingestion of grapefruit and grapefruit juice, patients should be constantly monitored, and blood levels should be obtained when indicated. These evaluations should ensure that when medical therapy is added, changed, or deleted, these adjustments do not have an impact on the effects of the cyclosporine.

Infection

Patients receiving cyclosporine and other calcineurin inhibitors have an increased risk of developing infections. Opportunistic infections associated with impaired cell-mediated immunity are particularly increased in these patients.

Renal Disease and Hypertension

Renal disease and hypertension are common adverse events during cyclosporine therapy and increase in prevalence with increased doses and duration of

therapy. Close monitoring of blood pressure and serum creatinine concentration is critical during treatment with cyclosporine. In many cases, these conditions are reversible if they are detected early and appropriate dose adjustments are implemented. In many patients, a mild increase in serum creatinine concentration may be tolerated if the level remains stable. Although renal abnormalities and hypertension are commonly identified during treatment with cyclosporine, most patients can continue taking the drug if adjustments in dose or other interventions are implemented to avoid these complications.

Malignant Neoplasia

Malignant neoplasms, particularly lymphomas, are more common in patients receiving solid organ transplants and immunosuppressive therapy. However, the exact cause of these malignant neoplasms has not been determined. In vitro mutagenesis assays with cyclosporine have been negative. In vivo animal studies have yielded equivocal results, with some data suggesting a possible increased rate of malignant neoplasms in rats and mice.

Reproductive Issues

Cyclosporine is a pregnancy class C drug. Data in animals have demonstrated toxicity to both the embryo and the fetus. Patients should practice effective contraception while receiving this drug. Data from pregnant transplant patients are difficult to interpret because cyclosporine is generally not the only medical therapy being given to these women, and the impact of the disease associated with organ transplantation may be difficult to separate from the impact of therapy. Despite these limitations, normal pregnancies and early childhood development have been reported in many women receiving cyclosporine and their children. Premature birth and low birthweight are more common among women receiving cyclosporine. Therefore, although the use of cyclosporine during pregnancy and breast-feeding should be avoided if possible, in patients who become pregnant, an assessment can determine whether the immunosuppressive therapy should be continued. In some cases, the risk of organ rejection with the discontinuation of cyclosporine therapy may exceed the risk of exposure to the fetus during pregnancy.

Other Adverse Effects

Cyclosporine has also been associated with the development of hirsutism, gingival hyperplasia, hyperuricemia, and electrolyte abnormalities.

Tacrolimus

Mechanism of Action

Whereas cyclosporine binds to cyclophilin, tacrolimus binds to a different protein, the 12-kD FK-binding protein (FKBP12). The binding of FKBP12 and tacrolimus forms a complex that inhibits calcineurin in a fashion similar to cyclosporine. Through this mechanism, tacrolimus has similar inhibitory effects on T-cell function and cytokine production.

Indications

Tacrolimus is approved for the prophylactic treatment of organ rejection after kidney and liver transplantation. Its efficacy and safety in rheumatoid arthritis are limited but encouraging. Experience with this agent is less extensive than that with cyclosporine.

Adverse Effects

The major adverse events associated with tacrolimus are similar to those associated with cyclosporine and include increased susceptibility to infection, renal disease, and hypertension. An increase in malignant neoplasia is also reported, with a pattern similar to that in patients receiving cyclosporine.

In addition to the adverse events similar to those reported with other calcineurin inhibitors, some specific complications have been reported with tacrolimus, including the development of post-transplantation diabetes mellitus. This was seen in 20% of subjects in phase III clinical trials of tacrolimus, with the onset generally occurring within the first 3 months of therapy. In many patients, post-transplantation diabetes mellitus resolves after the drug is discontinued. Neurotoxicity has been reported, including tremor, headache, motor function abnormalities, mental status alterations, and sensory changes. Myocardial hypertrophy has also been reported. Tacrolimus, like cyclosporine, is pregnancy class C; patients receiving this drug should practice effective contraception.

Sirolimus

Mechanism of Action

Sirolimus (or rapamycin) in not a calcineurin inhibitor, but it has many actions and mechanisms similar to that class of drug. The mechanism of action of sirolimus involves binding to FKBP12, the binding protein for tacrolimus, but the effect of this binding is different. Instead of acting on calcineurin, the sirolimus-FKBP12 complex binds to another protein, the mammalian target of rapamycin (mTOR), which is a key regulatory kinase. The inhibition of mTOR results in significant immunosuppression by decreasing T-cell proliferation and the progression from G_1 phase to S phase in the cell cycle. Because sirolimus works through a different mechanism of action from cyclosporine, the two drugs have been studied in combination. In renal transplantation patients, these two agents in combination have a greater immunosuppressive effect than that of cyclosporine alone.

Indications

Sirolimus is approved for the prophylaxis of organ rejection in renal transplantation patients older than 12 years, in combination with cyclosporine and corticosteroids. Data on the use of sirolimus in other populations, including subjects with autoimmune diseases, are limited and are generally derived from animal models.

Adverse Effects

The adverse event profile of sirolimus in terms of infections and malignant neoplasms is similar to that of the calcineurin inhibitors. Renal disease in patients taking cyclosporine and sirolimus in combination has been reported more frequently than in those receiving cyclosporine alone. Adverse reactions specific for sirolimus include hyperlipidemia, interstitial lung disease, and the syndrome of calcineurin-induced hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, and thrombotic microangiopathy.

Alkylating Agents

Alkylating agents are an important component of immunosuppressive therapy in autoimmune diseases. The use of these agents is limited by their toxicity, particularly the potential for the development of malignant neoplasia, reproductive toxicity, and an increased incidence of infection. Patients considered candidates for alkylating therapy should be fully informed of the potential risks and benefits of these drugs and should concur with the decision to use them. Regular monitoring of the CBC and urinalysis is important in patients receiving these drugs.

Cyclophosphamide

Cyclophosphamide has been used primarily as a cytotoxic drug for the treatment of malignant neoplasms; it is currently approved for this indication as well as for biopsy-proven minimal change nephrotic disease in children. Several severe autoimmune diseases are also responsive to cyclophosphamide, which is often given in conjunction with initial high-dose corticosteroid therapy. Because of the significant toxicities associated with these drugs, a benefit-to-risk assessment and discussion should be undertaken with each patient for whom cyclophosphamide is being considered. In most cases, the diseases warranting cyclophosphamide therapy are life-threatening conditions with a poor prognosis, justifying the use of such a toxic agent.

Mechanism of Action

Cyclophosphamide is an inactive compound that can be administered either orally or intravenously. It is metabolized to the active drug by the cytochrome P-450 mixed-function oxidase system. This process produces the active compounds phosphoramide mustard and the toxic metabolite acrolein. The cytotoxic effect of this drug results from the alkylation of various cellular constituents, especially nucleic acids. Changes in immune function with cyclophosphamide include depletion of lymphoid tissues, with decreases in both B and T cells, suppression of cellular immune function, and decreased antibody production.

Indications

The use of cyclophosphamide in the treatment of rheumatic diseases is most common and well studied in lupus nephritis and severe systemic vasculitis. Controlled clinical trials have demonstrated improved outcomes in these

conditions, with reduced progression to end-stage renal disease in patients with SLE and improved survival in those with systemic vasculitides such as Wegener's granulomatosis. The evaluation of cyclophosphamide in patients with SLE has demonstrated the benefit of intermittent, usually monthly, intravenous pulse therapy as a method to avoid some of the most severe toxic side effects while maintaining therapeutic efficacy. However, pulse intravenous cyclophosphamide is not as effective as continuous oral cyclophosphamide in all conditions, particularly Wegener's granulomatosis. Patients with other conditions, such as polyarteritis nodosa, Takayasu's arteritis, and Churg-Strauss syndrome, reportedly benefit from cyclophosphamide therapy; however, the low prevalence of these diseases has prohibited the conduct of controlled clinical trials to prove its efficacy. Cyclophosphamide is also effective in the treatment of rheumatoid arthritis, but it is generally not used in this condition because of its toxicity and the availability of other effective agents. Although the advent of cyclophosphamide has been a tremendous advance in the treatment of these life-threatening diseases, the use of less toxic medications with similar clinical efficacy is currently under investigation.

Adverse Effects

Before the initiation of cyclophosphamide therapy, a frank discussion with the patient about potential serious and even life-threatening adverse events should be undertaken and documented.

MALIGNANT NEOPLASIA. Malignant neoplasms may develop in patients receiving cyclophosphamide for the treatment of both malignant and nonmalignant diseases. The risk of malignant change appears to increase with the duration and dose of cyclophosphamide. The most common malignant neoplasms are bladder, myeloproliferative, and lymphoproliferative disorders. The use of intravenous pulse cyclophosphamide may reduce but not eliminate the risk of bladder cancer. These malignant neoplasms may develop years after discontinuation of the drug.

REPRODUCTIVE ISSUES. Cyclophosphamide can be teratogenic, affect female reproduction, and reduce male fertility. Cyclophosphamide is pregnancy category D and should not be used in pregnant women unless life-threatening disease is present that warrants this treatment. Although successful pregnancies have been reported in patients receiving cyclophosphamide during pregnancy, fetal abnormalities are well documented secondary to chromosome damage. The use of cyclophosphamide in premenopausal women can induce premature ovarian failure. The use of gonadotropin-releasing hormone analogues during intravenous pulse cyclophosphamide therapy may reduce but not eliminate the risk of premature ovarian failure in patients with SLE. In males, a temporary or permanent decrease in sperm count may occur with cyclophosphamide. Because the recovery of fertility after cyclophosphamide therapy is variable, sperm banking should be considered before treatment is begun.

OTHER ADVERSE EFFECTS. As with other immunosuppressive agents, infections are more frequent and potentially more serious in patients receiving cyclophosphamide. Opportunistic infections are more likely to be seen in these subjects. Hematologic abnormalities can involve all cell lines. The CBC should be monitored regularly, and cyclophosphamide should be discontinued or the dose reduced when cytopenias develop. Cyclophosphamide treatment may be complicated by hemorrhagic cystitis and bladder cancer, which are probably related to the toxic metabolite acrolein. Efforts to reduce the potential for hemorrhagic cystitis and malignant bladder neoplasms include the use of intravenous pulse therapy, hydration, frequent voiding, and treatment with agents containing sulfhydryl groups to scavenge acrolein. Regular urinalysis for blood is indicated to monitor for bladder toxicity. Patients may develop severe nausea, vomiting, and diarrhea with cyclophosphamide therapy.

Chlorambucil

Chlorambucil has not been evaluated as extensively as cyclophosphamide, but this agent appears to have similar properties and a similar adverse event profile. Like cyclophosphamide, chlorambucil is associated with the development of malignant neoplasms and should be avoided during pregnancy.

Miscellaneous Agents

Although principally prescribed for other indications, methotrexate and leflunomide have been evaluated and used for their potential immunosuppressive effects. Leflunomide blocks the enzyme dihydroorotate dehydrogenase, resulting in the inhibition of pyrimidine synthesis and a reduction in T-cell activation. Methotrexate has multiple mechanisms of action, but its major effect in autoimmune diseases is mediated by inhibition of the enzyme aminoimidazole-4-carboxamide ribonucleotide transformylase. This inhibition affects purine synthesis, increasing the intracellular concentration of aminoimidazole-4-carboxamide ribonucleotide, which stimulates the release of adenosine, a potent anti-inflammatory compound. Methotrexate has principally been advocated for its corticosteroid-sparing effects. Both methotrexate and leflunomide are effective DMARDs in the treatment of rheumatoid arthritis.

BIOLOGIC AGENTS

CEM GABAY

Biologic agents are a new class of therapeutic agents that target different mediators involved in the pathogenesis of human diseases. The development of these therapies has markedly improved the management of many diseases. In addition, their use has greatly increased our understanding of the pathophysiology of these diseases. One of the most compelling examples is the efficacy of tumor necrosis factor (TNF)-α inhibitors in rheumatoid arthritis and inflammatory bowel disease.

Classification systems for the different biologic therapies have been established (Table 35-1). The pharmaceutical company usually provides the prefix of the name, and the suffix defines whether this is a monoclonal antibody (mab), a soluble receptor (cept), or a kinase inhibitor (inib). Monoclonal antibodies, by far the largest group of biologic agents today, also include in their names the type of target (immune system, cancer, cardiovascular system, bone), as well as their origin (chimeric, humanized, human). Rather than providing an exhaustive review of all tested approaches, this chapter reviews the currently approved treatments.

TUMOR NECROSIS FACTOR-α INHIBITORS

The cytokine TNF-α binds to two different receptors, TNF-R55 and TNF-R75, and exerts important functions in the control of host responses against infection. However, uncontrolled TNF-α production may lead to chronic inflammation and subsequent tissue damage.

Types of TNF Inhibitors

Different agents have been developed to inhibit the biologic activity of TNF-α, including monoclonal antibodies and soluble receptors. Monoclonal antibodies include infliximab (Remicade), adalimumab (Humira), and golimumab (Simponi). Infliximab is a chimeric antibody, whereas the other two are fully human antibodies. Certolizumab-pegol (Cimzia) is a pegylated humanized anti–TNF-α antibody Fab′ fragment. Etanercept (Enbrel) is a fusion protein that contains the extracellular portion of TNF-R75 coupled to the Fc domain of human immunoglobulin (Ig) G1. All these agents bind to TNF-α and block its biologic activity. Etanercept also binds to lymphotoxin-α (previously termed TNF-β). Infliximab has been shown to exert cytotoxic effects on macrophages and T lymphocytes expressing TNF-α on their surface.

Indications

TNF-α antagonists are approved for the treatment of rheumatoid arthritis (Chapter 272). They exert marked anti-inflammatory effects and prevent the progression of structural joint damage. TNF-α inhibitors are efficacious in

TABLE 35-1 NOMENCLATURE OF MONOCLONAL ANTIBODIES

Nomenclature for monoclonal antibodies (mAbs) are composed of a prefix, a substem A, a substem B, and a suffix.
The common stem for all mAbs is *–mab*, placed as a suffix.
Substems B and A preceding *–mab* represent source identifiers of the antibody, as follows:

TARGET (MOLECULE, CELL, ORGAN)	SUBSTEM A
Immunomodulating	*-l(i)-*
Cardiovascular	*-c(i)-*
Bone	*-o(s)-*
Interleukin	*-k(i)-*
Tumor	*-t(u)-*
SOURCE	**SUBSTEM B**
Human	*-u-*
Humanized	*-zu-*
Chimeric	*-xi-*
Rat	*-a-*
EXAMPLE	**INDICATES**
Ri***tuxi***mab	**Tumor, chimeric**
Den**osu**mab	**Bone, human**
Tras***tuzu***mab	**Tumor, humanized**
Beva***cizu***mab	**Cardiovascular, humanized**

From the International Nonproprietary Names (INN) Program of the World Health Organization, 2009: www.who.int/medicines/services/inn/Generalpoliciesformonoclonalantibodies2009.pdf.

early rheumatoid arthritis and in long-standing disease refractory to conventional disease-modifying antirheumatic drugs (DMARDs) such as methotrexate. TNF-α inhibitors are also approved for the treatment of ankylosing spondylitis refractory to nonsteroidal anti-inflammatory drugs (NSAIDs) and psoriatic arthritis refractory to DMARDs (Chapter 273). Anti–TNF-α antibodies, but not etanercept, have proven efficacy in severe Crohn's disease (Chapter 143) by reducing the disease activity score, inducing closure of draining fistulas, and allowing a decrease in the dose of chronic glucocorticoid medication. Infliximab is approved for the treatment of ulcerative colitis refractory to conventional therapy. Infliximab, adalimumab, and etanercept are also approved for the treatment of chronic plaque psoriasis (Chapter 446) refractory to phototherapy or systemic therapy.

Adverse Effects

TNF-α inhibitors can cause allergic reactions. Postmarketing data have shown that TNF-α inhibitors are associated with an increased risk of infections, including all types of bacterial and opportunistic infections. In particular, the use of TNF-α inhibitors has been associated with an increased risk of reactivation of latent tuberculosis. The results of cohort studies do not support an increased risk of cancer. Rare cases of demyelinating disorders, lupus-like manifestations, and cytopenia have also been reported.

INTERLEUKIN-1 INHIBITORS

Interleukin (IL)-1 (both IL-1α and IL-1β) binds to IL-1 receptors (type I IL-1R and IL-1R accessory protein) to induce a vast array of inflammatory signals. IL-1 receptor antagonist (IL-1Ra) competitively inhibits the interaction of IL-1 with its receptors.

Types of IL-1 Inhibitors

Anakinra (Kineret), recombinant human IL-1Ra, was the first IL-1 inhibitor used in clinical trials. Rilonacept (Arcalyst) is a fusion protein including the IL-1 binding motifs of IL-1 receptors coupled to the Fc domain of human IgG1. Canakinumab (Ilaris) is a fully human monoclonal antibody against IL-1β.

Indications

Anakinra is approved for the treatment of rheumatoid arthritis refractory to conventional DMARDs, but it has relatively modest efficacy. Anakinra, canakinumab, and rilonacept exert marked anti-inflammatory effects in hereditary systemic autoinflammatory diseases (Chapter 269) characterized by enhanced IL-1β production, leading to their approval for this indication. Anakinra is effective in some patients with systemic inflammatory diseases, including systemic-onset juvenile idiopathic arthritis, adult-onset Still's disease, and other autoinflammatory conditions. Clinical trials have reported encouraging results in crystal-induced arthritis such as gout and chondrocalcinosis. Promising results have also been reported from the use of anakinra in type 2 diabetes mellitus and smoldering/indolent multiple myeloma.

Adverse Effects

Anakinra is frequently associated with injection site reactions. A modest increase in serious infections has been reported with anakinra. The combination of anakinra and etanercept (and probably other TNF-α antagonists as well) increases the risk of infections and is not recommended.

INTERLEUKIN-6 INHIBITORS

IL-6 is a pro-inflammatory cytokine that binds to a heterodimeric receptor, including IL-6Rα and gp130. Tocilizumab (Actemra) is a humanized monoclonal antibody against IL-6Rα that inhibits its interaction with IL-6.

Indications

Tocilizumab is approved for the treatment of rheumatoid arthritis refractory to conventional DMARDs and TNF-α antagonists. In clinical trials, tocilizumab prevented the progression of radiographic damage. Tocilizumab is also effective in controlling the inflammatory manifestations of systemic-onset juvenile idiopathic arthritis. Clinical trials are in progress in other inflammatory rheumatic diseases.

Adverse Effects

Tocilizumab has been associated with an increased risk of serious infections. A transient increase in transaminase levels has been reported. Hypercholesterolemia and cytopenia may appear in some patients.

ANTIBODY AGAINST INTERLEUKIN-12 AND INTERLEUKIN-23

IL-12 and IL-23 are heterodimeric cytokines, including a common p40 subunit and a specific subunit—p35 for IL-12, and p19 for IL-23. IL-23 participates in the differentiation of T_H17 cells that produce IL-17. Recent experimental findings indicate that IL-23 and IL-17 are critical for the development of autoimmune pathologies. Ustekinumab (Stelara) is a human monoclonal antibody against p40 that targets both IL-12 and IL-23 and blocks their biologic activities.

Indications

Ustekinumab is approved for the treatment of psoriasis in patients who have had prior exposure to phototherapy or other systemic therapies. In clinical trials, ustekinumab was associated with the successful treatment of Crohn's disease. In addition, ustekinumab was effective in patients with psoriatic arthritis refractory to conventional DMARDs. Anti–IL-17 antibodies are also in clinical trials for the treatment of psoriasis and rheumatoid arthritis.

Adverse Effects

Ustekinumab has been well tolerated in clinical trials.

INHIBITORS OF ANGIOGENESIS

Vascular endothelial growth factor (VEGF) is a family of growth factors involved in vasculogenesis and angiogenesis. VEGF-A binds to the tyrosine kinase receptors VEGFR1 and VEGFR2. VEGF has been implicated in tumor growth and metastasis, in diabetic retinopathy, and in age-related macular retinopathy.

Types of Angiogenesis Inhibitors

Bevacizumab (Avastin) is a humanized monoclonal antibody against VEGF that acts as an angiogenesis inhibitor. VEGF Trap is a fusion protein containing extracellular immunoglobulin motifs of VEGFR1 and VEGFR2 coupled to human IgG1. Sunitinib (Sutent) and sorafenib (Nexavar) are two orally available tyrosine kinase inhibitors that block not only VEGFR2 but also platelet-derived growth factor receptor β, C-kit, and Flt3 receptor.

Indications

Bevacizumab is approved for the treatment of glioblastoma (Chapter 195) and also for some patients with non–small cell lung cancer (Chapter 197) and metastatic colorectal cancer (Chapter 199). The absence of clear benefit on survival in patients with metastatic breast cancer led to the removal of the indication by the FDA. Bevacizumab is still approved in Europe in combination with placitaxel for this indication. Intraocular injections of ranibizumab (Lucentis), an antibody fragment derived from bevacizumab, are effective in maintaining vision in the vast majority of patients with wet macular degeneration (Chapter 431) and are approved for this indication.

Sunitinib is approved for the treatment of metastatic renal cell carcinoma (Chapter 203) and gastrointestinal stromal tumor refractory to imatinib (Chapter 209). Sorafenib is approved for advanced renal cell carcinoma and some cases of hepatocarcinoma (Chapter 202).

Adverse Effects

Bevacizumab has been associated with a heightened risk of bleeding and gastrointestinal tract perforation. Delayed wound healing and hypertension have also been reported. Sunitinib and sorafenib are generally well tolerated. Reported adverse events include hypertension, fatigue, asthenia, diarrhea, and some abnormal laboratory tests, including lipase, amylase, leukocytes, and platelets.

INHIBITORS OF TUMOR GROWTH FACTORS

Epidermal growth factor receptor (EGFR), a member of the ErbB-1 (HER-1) family of receptors, is a cell surface receptor for EGF and transforming growth factor-α. Binding of EGFR tyrosine kinase activity leads to increased gene transcription, cell proliferation, and inhibition of apoptosis. Human epithelial growth factor receptor (HER)-2 (also known as ErbB-2) is a receptor with tyrosine kinase activity that is expressed at high levels in 20 to 30% of breast cancers and other types of cancers and may cause uncontrolled tumor cell proliferation.

Types of Tumor Growth Factor Inhibitors

Two types of strategies target the EGFR pathway: monoclonal antibodies to the extracellular domain of EGFR, and orally available tyrosine kinase inhibitors. Cetuximab (Erbitux) is a chimeric monoclonal IgG1 anti-EGFR antibody that inhibits EGFR signaling and may also induce tumor cell death by antibody-dependent cellular cytotoxicity. Panitumumab (Vectibix) is a fully human monoclonal IgG2 antibody directed against EGFR. Erlotinib (Tarceva) and gefitinib (Iressa) are the two most commonly studied EGFR tyrosine kinase inhibitors.

Trastuzumab (Herceptin) is a humanized monoclonal IgG1 antibody that binds to the extracellular domain of HER-2. Lapatinib (Tykerb) is a small molecule with inhibitory activity on EGFR and HER-2 tyrosine kinases.

Indications

Cetuximab is an approved second- and third-line treatment for colorectal cancer and squamous cell carcinoma of the head and neck. Positive results were also reported in clinical trials of cetuximab as first- or second-line treatment in patients with non–small cell lung cancer. Panitumumab is approved for the treatment of metastatic colorectal cancer. Erlotinib is approved for the treatment of metastatic non–small cell lung carcinoma and advanced pancreatic cancer, and gefitinib is approved for the treatment of advanced non–small cell lung carcinoma. Trastuzumab and lapatinib are approved for the treatment of metastatic breast cancer expressing HER-2.

Adverse Effects

Cetuximab is sometimes associated with severe allergic reactions during infusion. Acne-like skin rash is commonly reported. Erlotinib and gefitinib are associated with acne-like rash and mild gastrointestinal symptoms. Cardiotoxicity is a major problem in patients treated with trastuzumab. Approximately 10% of patients are unable to tolerate this drug because of preexisting heart problems. The risk of cardiomyopathy is increased when combined with anthracycline (which itself is associated with cardiac toxicity). Lapatinib is generally well tolerated, but some cases of hepatotoxicity have been reported.

OTHER TYROSINE KINASE INHIBITORS

Imatinib mesylate (Gleevec, Glivec) works by binding to the adenosine triphosphate (ATP) binding site of Bcr-abl, resulting in competitive inhibition of its enzymatic activity. Imatinib also inhibits the tyrosine kinase activity of C-kit and platelet-derived growth factor receptor.

Indications

Imatinib represents a major advance over conventional treatments for chronic myelogenous leukemia (Chapter 190), with more than 90% of patients obtaining a complete hematologic response and 70 to 80% achieving a complete cytogenetic response. Resistance to imatinib is often a result of point mutations causing a conformation change in Bcr-abl, which impairs imatinib binding. Dasatinib (Sprycel) and nilotinib (Tasigna), two other tyrosine kinase inhibitors, are approved for the treatment of chronic myelogenous leukemia that is not responsive or is intolerant to imatinib, and dasatinib can provide more rapid and possibly durable responses than does imatinib.

Imatinib is also approved for the treatment of patients with C-kit–positive advanced gastrointestinal stromal tumor (Chapter 209). Early clinical trials also showed imatinib's potential beneficial effects in systemic mastocytosis, hypereosinophilic syndrome, and dermatofibrosarcoma protuberans. Imatinib is in clinical trials for systemic sclerosis.

Adverse Effects

Imatinib has been associated with cytopenia, edema, nausea, and rash, as well as rare cases of congestive heart failure. Cytopenia and congestive heart failure are also reported with dasatinib, and cytopenia can occur with nilotinib. The latter drug also carries a potential risk of severe cardiac arrhythmias.

BIOLOGIC AGENTS TARGETING T LYMPHOCYTES

T cells play a central role in immune responses and are thus important targets for therapies against graft rejection and autoimmune diseases.

Types of Agents Modulating T-Cell Activity

The agents targeting T cells include antibodies against T cells, soluble receptors inhibiting costimulation signals, and antibodies blocking T-cell migration. Therapies targeting CD3 were developed more than 30 years ago with a mouse monoclonal IgG2 antibody called OKT3. These antibodies were used in the treatment of kidney transplant rejection but were associated with limiting side effects due to the occurrence of a "cytokine release syndrome." A series of non-Fc binding humanized anti-CD3 monoclonal antibodies was developed to overcome this problem, along with the development of antimurine immunoglobulin antibodies.

Abatacept (Orencia) is a fusion protein containing the extracellular portion of cytotoxic T-lymphocyte antigen-4 coupled to the Fc portion of human IgG1; it inhibits costimulatory signals between CD28 and CD80/86. Alefacept (Amevive) is a recombinant fully human fusion protein in which the extracellular domain of CD2 has been linked to the Fc portion of IgG1; it inhibits costimulatory signals between CD2 and LFA-3.

Natalizumab (Tysabri), a humanized monoclonal antibody against α_4-integrin, inhibits the migration of T cells by blocking the interaction between α_4-integrin and adhesion molecules expressed on endothelial cells.

Indications

Different monoclonal anti-CD3 antibodies are used in clinical trials for the prevention of transplant rejection (Chapter 48), as well as for the treatment of acute graft-versus-host disease and type 1 diabetes mellitus.

Abatacept is approved for the treatment of rheumatoid arthritis refractory to conventional DMARDs and TNF-α inhibitors. Positive results have been reported in psoriasis and psoriatic arthritis. Alefacept is approved for the treatment of chronic plaque psoriasis. Natalizumab is approved for the treatment of patients with highly active remitting-relapsing multiple sclerosis on monotherapy (Chapter 419) and for severe Crohn's disease.

Adverse Effects

Abatacept is generally well tolerated, but serious infections may occur. Lymphopenia may occur with alefacept, and infections, malignancies, and hepatotoxicity have been reported in clinical trials. Natalizumab can be associated with allergic reactions and hepatotoxicity. Some cases of multifocal progressive leukoencephalopathy (Chapter 378), a fatal neurologic complication of JC virus reactivation in immunosuppressed individuals, have been reported, thus limiting the use of natalizumab.

BIOLOGIC AGENTS TARGETING B LYMPHOCYTES

The B-cell lineage plays a critical role in immune responses through the production of immunoglobulins, the presentation of antigen to T cells, and the production of cytokines. Therapies targeting B cells are used in B-cell lymphoma and autoimmune diseases.

Mode of Action

B cells can be targeted either by the use of monoclonal antibodies depleting B cells or by the inhibition of cytokines essential for their maturation and survival, such as B-cell activating factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL). Rituximab (Rituxan, MabThera), ofatumumab (Arzerra), and ocrelizumab are B-cell–depleting monoclonal antibodies binding to CD20. Belimumab is a fully human monoclonal antibody against BAFF. Atacicept is a fusion protein containing the extracellular domain of TACI (BAFF and APRIL receptor), which inhibits BAFF and APRIL biologic activities.

Indications

Rituximab is approved for the treatment of non-Hodgkin's B-cell lymphoma (Chapter 191). More recently, rituximab has also been approved for rheumatoid arthritis patients with an inadequate response to TNF-α inhibitors. Ofatumumab is approved for the treatment of chronic lymphocytic leukemia (Chapter 190). Ocrelizumab is currently in clinical trials in multiple sclerosis and systemic lupus erythematosus. Epratuzumab, a humanized monoclonal anti-CD22 B-cell–depleting antibody, is in clinical trials for non-Hodgkin's B-cell lymphoma and systemic lupus erythematosus.

The administration of belimumab in patients with systemic lupus erythematosus has led to positive results regarding the number of flares and disease activity. Atacicept is in clinical trials for rheumatoid arthritis and systemic lupus erythematosus.

Adverse Effects

Rituximab is associated with an allergic reaction during infusions, a systemic reaction due to tumoral B-cell lysis, and an increased risk of infections. Rare cases of multifocal progressive leukoencephalopathy have been reported. Hypogammaglobulinemia may occur, particularly after several series of infusions.

CONCLUSIONS

The use of biologic agents has led to major advances in the management of many severe diseases refractory to conventional therapies. These agents have also provided a unique way to confirm the role of basic mechanisms in human diseases. New developments in this field will take different directions, including the refinement of existing strategies (using more selective inhibitors or human rather than chimeric antibodies), the extension to indications other than those for which the agents were primarily designed, and the selection of novel targets.

PROSTANOIDS, ASPIRIN, AND RELATED COMPOUNDS

CARLO PATRONO

Arachidonic acid, or 5,8,11,14-eicosatetraenoic acid, is a 20-carbon polyunsaturated fatty acid esterified in the phospholipid domain of cell membranes. In response to chemical, physical, and hormonal stimuli, arachidonic acid is released from the glycerol backbone sn-2 position by the action of various phospholipases A_2, and can be subjected to rapid enzymatic conversion to a series of oxygenated derivatives collectively called *eicosanoids*. The enzymes catalyzing various structural modifications of free arachidonic acid include prostaglandin H synthases (commonly known as *cyclooxygenases* [COX]), *lipoxygenases*, and *cytochrome P-450 isozymes*. The resulting eicosanoids include prostanoids (prostaglandins and thromboxane A_2), leukotrienes, lipoxins, and epoxylins. Esterified arachidonic acid can also be subjected to in situ peroxidation, catalyzed by oxygen radicals, to form a series of corresponding isomers called *isoeicosanoids*.

Eicosanoids are not stored but are produced in response to diverse stimuli, with a pattern that reflects the cell-specific distribution of arachidonic acid–metabolizing enzymes and downstream isomerases and synthases. Eicosanoids are not circulating hormones but rather ubiquitous autacoids that modulate the intensity and duration of many important cellular responses in an autocrine (acting on the same cells that produced them) or paracrine (acting on nearby cells) fashion.

BIOSYNTHESIS AND ACTION OF PROSTANOIDS

Prostanoids include prostaglandins D_2, E_2, $F_{2\alpha}$, and I_2 (prostacyclin) and thromboxane A_2. They are formed through the sequential actions of phospholipase A_2 to release arachidonic acid from membrane phospholipids, prostaglandin H synthase to catalyze the cyclooxygenation of arachidonic acid to form the unstable intermediate prostaglandin G_2 and its reduction to prostaglandin H_2, and specific isomerases and synthases to catalyze the conversion of prostaglandin H_2 to different prostanoids (Fig. 36-1). Once formed, prostanoids interact with specific G protein–coupled receptors to evoke a variety of cellular responses, depending on the site of their biosynthesis (see Fig. 36-1).

Two prostaglandin H synthases have been identified: prostaglandin H synthase-1 is expressed constitutively in all cells; prostaglandin H synthase-2 is constitutively expressed in some cells (e.g., neurons and renal cells) and is induced in other cell types in response to cytokines (e.g., in monocytes), tumor promoters (e.g., in intestinal epithelial cells), growth factors (e.g., in bone marrow–derived stem cells), and laminar shear stress (e.g., in endothelial cells). Because nonsteroidal anti-inflammatory drugs (NSAIDs) target the COX activity of these enzymes, they have become known colloquially as COX-1 and COX-2. Both enzymes are homodimers that convert arachidonic acid, two O_2 molecules, and two electrons from one or more unknown reductants to prostaglandin H_2. COX-1 and COX-2 are found predominantly in the same cellular organelles, at the luminal surface of the endoplasmic reticulum and nuclear envelope of cells. Only one monomer of a dimer catalyzes arachidonic acid oxygenation at any given time. The cross-talk between monomers serves as a way for COX-2 to exhibit selectivity toward arachidonic acid, even when it is a minor component of the available fatty acid pool, and to sustain a "late phase" of prostanoid production. In contrast, COX-1 may efficiently oxygenate arachidonic acid in the early phase of prostanoid production, when this substrate represents a large fraction of free fatty acids, but may be inhibited by other competing fatty acids in the late phase.

Phenotypical analyses of COX-1-deficient and COX-2-deficient mice, as well as studies with isoform-selective inhibitors, suggest that there are processes in which each isozyme is uniquely involved (e.g., platelet aggregation for COX-1, ovulation and neonatal development for COX-2) and others in which both isozymes function coordinately (e.g., inflammation and its resolution, gastrointestinal ulceration and healing, and carcinogenesis). A way in which the two biosynthetic pathways may be dissociated metabolically is by a preferential coupling of the COX isozymes to various upstream phospholipases and downstream synthases, conditioning preferential formation of a particular prostanoid by a given cell type (e.g., COX-2-dependent prostacyclin by vascular endothelial cells).

Moreover, COX-2 oxygenation may play a unique role in a novel signaling pathway dependent on agonist-induced release of endocannabinoids. Among the products of COX-2 oxygenation of endocannabinoids are glyceryl prostaglandins, some of which (e.g., glyceryl prostaglandin E_2 and glyceryl prostaglandin I_2) exhibit interesting biologic activities in inflammatory, neurologic, and vascular systems.

MEASUREMENTS OF THE PROSTAGLANDIN H SYNTHASE PATHWAY

Prostanoids are formed in vivo at a relatively low rate (e.g., 0.1 ng/kg per minute for both prostacyclin and thromboxane A_2) and are metabolized extensively by lung and liver enzymes to form chemically stable, but biologically inactive, derivatives that are excreted primarily through the kidney. Given the chemical instability and extremely low concentrations (1 to 2 pg/

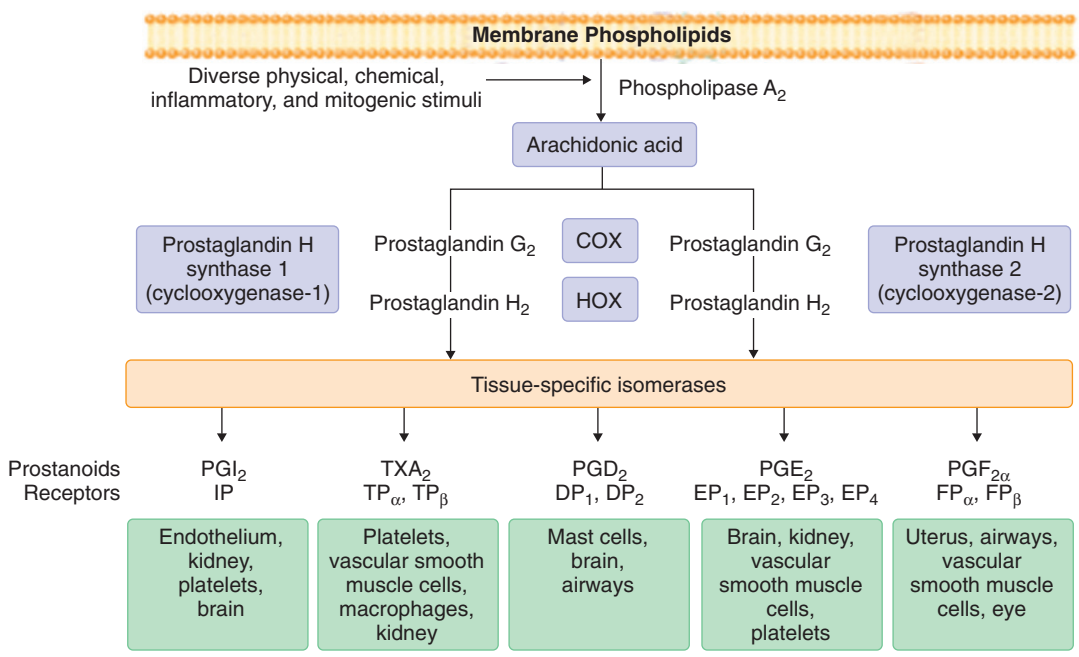

FIGURE 36-1. Production and actions of prostaglandins and thromboxane. Arachidonic acid, a 20-carbon fatty acid containing four double bonds, is liberated from the *sn*2 position in membrane phospholipids by phospholipase A_2, which is activated by diverse stimuli. Arachidonic acid is converted by prostaglandin H synthases, which have both cyclooxygenase (COX) and hydroperoxidase (HOX) activity, to the unstable intermediate prostaglandin H_2. The synthases are colloquially termed *cyclooxygenases* and exist in two forms, cyclooxygenase-1 and cyclooxygenase-2. Prostaglandin H_2 is converted by tissue-specific isomerases to multiple prostanoids. These bioactive lipids activate specific cell membrane receptors of the superfamily of G protein–coupled receptors. Some of the tissues in which individual prostanoids exert prominent effects are indicated. IP denotes prostacyclin receptor, TP thromboxane receptor, DP prostaglandin D_2 receptor, EP prostaglandin E_2 receptor, and FP prostaglandin $F_{2\alpha}$ receptor.

mL) of prostanoids in the systemic circulation, assessment of their production in humans is largely based on measurements of stable urinary metabolites (e.g., 11-dehydro-thromboxane B_2, a major enzymatic derivative of thromboxane A_2, and 2,3-dinor-6-keto-$PGF_{1\alpha}$, a major enzymatic derivative of prostacyclin). These analytical measurements have established that thromboxane metabolite excretion is primarily derived from platelet thromboxane biosynthesis and largely reflects the rate of platelet activation in vivo. Similarly, prostacyclin metabolite excretion largely reflects the rate of vascular prostacyclin biosynthesis in vivo. Thromboxane biosynthesis is persistently enhanced in association with the major cardiovascular risk factors (e.g., diabetes mellitus). Both thromboxane and prostacyclin biosynthesis are episodically increased in patients with acute coronary syndromes, perhaps reflecting a homeostatic response to accelerated platelet-vascular interactions.

Studies of the human pharmacology of COX inhibitors have largely relied on the development of whole blood assays of platelet COX-1 (based on serum thromboxane B_2 measurements) and monocyte COX-2 (based on lipopolysaccharide-induced prostaglandin E_2 production) activities. These assays have been useful in characterizing the variable potency of NSAIDs in inhibiting COX-1 and COX-2 in vitro (a measure of isozyme selectivity) and in determining ex vivo the dose- and time-dependence of their inhibitory effects in health and disease.

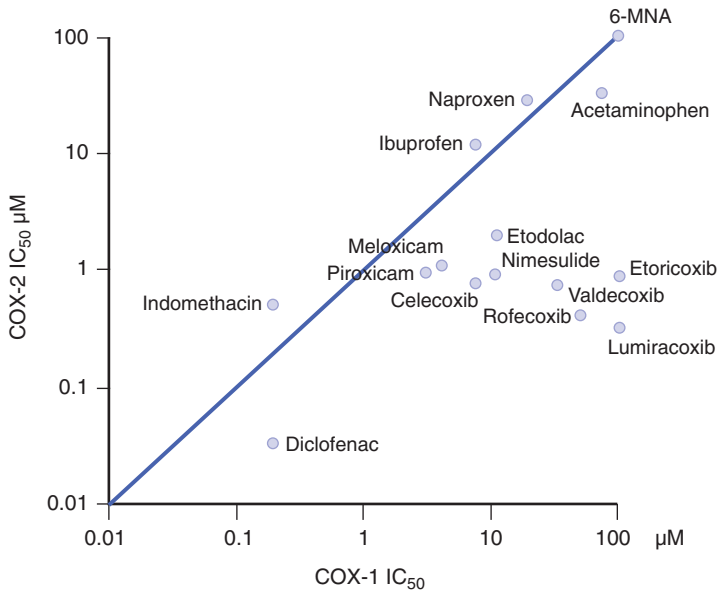

FIGURE 36-2. COX-2 selectivity as a continuous variable. Concentrations of various COX-2 inhibitors to inhibit the activity of platelet COX-1 and monocyte COX-2 by 50% (IC_{50}) are plotted on the abscissa and ordinate scales, respectively. The *solid line* describes equipotent inhibition of both COX-1 and COX-2. Symbols to the left of this line denote greater inhibition of COX-1 than COX-2. Symbols to the right of this line indicate progressively greater inhibition of COX-2 than COX-1, that is, increasing degrees of COX-2 selectivity. Aspirin is not shown on the figure because the long-term incubation required for monocyte COX-2 expression in human whole blood affects the chemical stability of the drug and underestimates its inhibitory potency. 6-MNA denotes 6-methoxy-2-naphthylacetic acid, the active metabolite of nabumetone.

CLINICAL PHARMACOLOGY OF PROSTAGLANDIN H SYNTHASE INHIBITION

Most traditional NSAIDs inhibit COX-1 and COX-2 with similar potency (Fig. 36-2). Some traditional NSAIDs (e.g., nimesulide and diclofenac) and a class of COX-2 inhibitors called coxibs (e.g., celecoxib and etoricoxib) are more potent in inhibiting COX-2 than COX-1 (see Fig. 36-2). These drugs fall into three general categories based on their mechanism of action. One category of inhibitors includes freely reversible competitive inhibitors, such as ibuprofen and mefenamic acid. Binding of these inhibitors to the COX sites of both monomers comprising a dimer is required for inhibition of COX-2 oxygenation of the substrate. A second group of inhibitors, including flurbiprofen, meclofenamate, diclofenac, and indomethacin, comprises time-dependent, noncovalent inhibitors. These NSAIDs are allosteric inhibitors that bind to one monomer of COX to inhibit its activity. Aspirin is unique to a third group of inhibitors that cause a time-dependent, covalent inhibition. Binding of aspirin to COX-1 or COX-2 leads to irreversible acetylation of a highly conserved serine residue (Ser-529 and Ser-516 in human COX-1 and COX-2, respectively). Aspirin acetylates only one monomer of a COX-1 dimer to cause complete loss of COX activity. Aspirin also maximally acetylates one monomer of human COX-2. The acetylated monomer of aspirin-treated COX-2 forms 15-hydroperoxyeicosatetraenoic acid from arachidonic acid, whereas the nonacetylated partner monomer forms mainly prostaglandin H_2 but only at 15 to 20% of the rate of native COX-2. Thus, the effect of

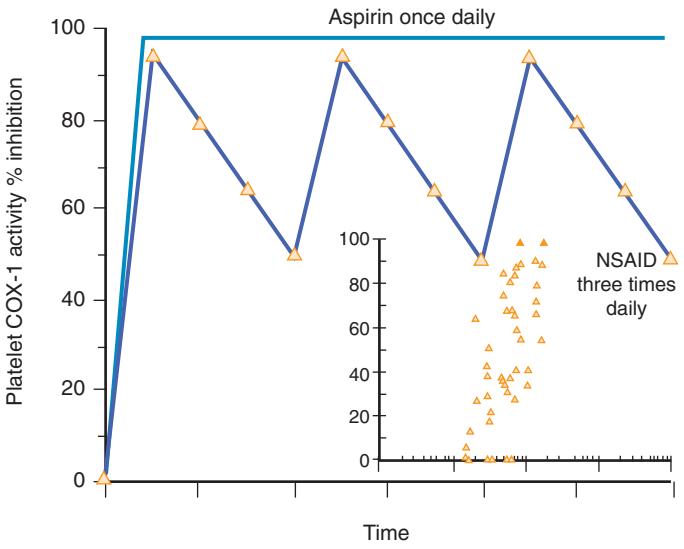

FIGURE 36-3. Time-dependent inhibition of platelet COX-1 activity by aspirin and a traditional nonsteroidal anti-inflammatory drug (NSAID). The average time course of inhibition of serum TXB_2, an ex vivo index of platelet COX-1 activity, is depicted over 24 hours following the administration of low-dose aspirin once daily and a traditional NSAID with short half-life given every 8 hours. The *inset* depicts the interindividual variability in the relationship between NSAID plasma levels plotted on the abscissa log scale and the corresponding level of inhibition of platelet COX-1 plotted on the ordinate.

TABLE 36-1 VASCULAR DISORDERS FOR WHICH ASPIRIN HAS BEEN SHOWN TO BE EFFECTIVE AND THE LOWEST EFFECTIVE DOSE

DISORDER	LOWEST EFFECTIVE DAILY DOSE (MG)
TIA and ischemic stroke*	50
Men at high cardiovascular risk	75
Essential hypertension	75
Chronic stable angina	75
Unstable angina or NSTEMI*	75
Severe carotid artery stenosis*	75
Polycythemia vera	100
Acute ischemic stroke*	160
Acute STEMI	162

*Higher doses were tested and not found to confer any greater risk reduction.
NSTEMI = non–ST elevation myocardial infarction; STEMI = ST elevation myocardial infarction; TIA = transient ischemic attack.

aspirin on COX-2 is an incomplete allosteric inhibition compared with that seen with COX-1.

Traditional NSAIDs typically inhibit platelet COX-1 and monocyte COX-2 by 50 to 90%, depending on dose; this effect is usually transient, depending on dose and half-life (Fig. 36-3). Coxibs inhibit monocyte COX-2 to the same extent as other NSAIDs, while substantially sparing platelet (and presumably other cells) COX-1 in most patients exposed to therapeutic doses. In contrast, aspirin achieves virtually complete (i.e., >97%) and persistent (i.e., ≥ 24 hour) inactivation of platelet COX-1 by virtue of its irreversible mechanism of action and inability of anucleate platelets to resynthesize the enzyme. Aspirin is equally potent in acetylating COX-1 and COX-2 in vitro. However, its unique mechanism of action and unusual pharmacokinetic features (20-minute half-life; presystemic encounter with the platelet target in the portal blood before first-pass liver metabolism) allow selective, cumulative inhibition of platelet COX-1 at low doses while substantially sparing vascular COX-2. The effect of aspirin on COX-1-dependent TXA_2 production is saturable at daily doses as low as 30 to 50 mg; in contrast, its inhibitory effect on COX-2-dependent prostaglandin I_2 biosynthesis is dose dependent up to daily doses of 650 to 1300 mg.

The relationships among inhibition of COX isozyme activity, reduced prostanoid formation, and changes in prostanoid-dependent cell function in vivo are not necessarily linear. The strikingly nonlinear relationship between inactivation of platelet COX-1 and inhibition of thromboxane-dependent platelet activation in vivo has important clinical implications for the cardiovascular effects of low-dose aspirin versus traditional NSAIDs (see later). In addition, interindividual variability in drug plasma levels as well as in the corresponding level of COX isozyme inhibition contributes to substantial unpredictability of the individual clinical response to COX inhibitors (E-Fig. 36-1).

Low-Dose Aspirin as an Antithrombotic and Anti-cancer Agent

The efficacy and safety of aspirin as an antithrombotic agent have been evaluated in several populations, ranging from apparently healthy persons at low risk of vascular complications (so-called primary prevention) to high-risk patients presenting with or surviving an acute myocardial infarction or an acute ischemic stroke (so-called secondary prevention). The clinical efficacy of aspirin was demonstrated at doses ranging from 50 to 162 mg given once daily (Table 36-1), consistent with the irreversible nature of its mechanism of action. Furthermore, higher doses (e.g., 300 to 325 mg) were not found to confer additional benefits, consistent with saturability of platelet COX-1 acetylation at low doses.■

In the six primary prevention trials among 95,000 low-risk individuals, aspirin allocation yielded a 12% relative risk reduction in serious vascular events (myocardial infarction, stroke, or vascular death).■ This protective effect was mainly due to a reduction in nonfatal myocardial infarction. The net effect on stroke was not significant, reflecting a small reduction in presumed ischemic stroke and counterbalancing effects on hemorrhagic stroke and other (probably ischemic) stroke. There was no significant reduction in vascular mortality. Aspirin increased gastrointestinal (or other extracranial) bleeds by approximately 50%.■

In 16 secondary prevention trials in 17,000 high-risk patients with prior myocardial infarction, or prior stroke or transient cerebral ischemia, aspirin allocation yielded 19% fewer serious vascular events, with similar proportional reductions in coronary events (20% relative risk reduction) and ischemic stroke (22% relative risk reduction) but a nonsignificant increase in hemorrhagic stroke.■ The absolute benefit of aspirin was about 25 times larger in secondary than in primary prevention (15 vs. 0.6 fewer vascular events per 1000 per year). In both primary and secondary prevention trials, the proportional reductions in serious vascular events appeared similar for men and women and for older and younger people. The risks of serious vascular events and of major extracranial bleeds were predicted by the same independent risk factors (age, male gender, diabetes mellitus, current smoking, blood pressure, and body mass index), so those with high risk of vascular complications also had a high risk of bleeding.

For secondary prevention of cardiovascular disease, the net benefits of adding aspirin to other preventive measures (e.g., statins) substantially exceed the bleeding hazards, irrespective of age and gender. In addition, aspirin, 75 mg daily or more for at least several years, reduces the incidence and mortality of colorectal cancer.■

Traditional Nonsteroidal Anti-inflammatory Drugs and Coxibs

NSAIDs constitute a chemically heterogeneous group of compounds that provide symptomatic relief of pain and inflammation associated with a variety of human disorders, including the rheumatic diseases. Their shared therapeutic actions (i.e., analgesic, anti-inflammatory, and antipyretic) are usually accompanied by mechanism-based adverse effects on gastrointestinal, cardiovascular, and renal functions. Prostanoids reproduce the main signs and symptoms of the inflammatory response and cause hyperalgesia and fever. Because of the redundancy of mediators of these responses, it is not surprising that NSAIDs only exert a moderate anti-inflammatory effect, are effective only against pain of low to moderate intensity and reduce fever, but do not interfere with the physiologic control of body temperature. The analgesic, anti-inflammatory, and antipyretic actions of traditional NSAIDs are largely reproduced by coxibs, a class of selective inhibitors of COX-2.

COX-2 selectivity is a continuous variable (see Fig. 36-2). Thus, one can pragmatically characterize three levels of COX-2 selectivity in terms of the probability of sparing COX-1 at therapeutic plasma levels: low (e.g., acetaminophen), intermediate (e.g., celecoxib, nimesulide, and diclofenac), and high (e.g., rofecoxib, etoricoxib, and lumiracoxib).

NSAIDs can modify the pharmacokinetics or pharmacodynamics of other drugs given concurrently, resulting in clinically important drug interactions. A pharmacodynamic interaction may occur between most NSAIDs and several classes of antihypertensive drugs. Reduced production of vasodilator prostacyclin and natriuretic prostaglandin E_2, as a consequence of renal

COX-2 inhibition, results in vasoconstriction and sodium and water retention that in turn tend to elevate blood pressure, regardless of the mechanism of action of antihypertensive drugs. This pharmacodynamic interaction has been described with most traditional NSAIDs (including acetaminophen) and coxibs, but not with low-dose aspirin.

Some NSAIDs favoring COX-1 over COX-2 inhibition, such as ibuprofen and naproxen, may interfere with the antiplatelet effect of low-dose aspirin by competing with acetylsalicylic acid for a common docking site (arginine-120) within the COX-1 channel. Drugs favoring COX-2 versus COX-1 inhibition, such as acetaminophen and diclofenac, do not interfere with the pharmacodynamic effect of low-dose aspirin, similarly to celecoxib and rofecoxib.

Upper gastrointestinal complications (bleeds, perforations, and obstructions) occur in 1 to 2% of NSAID-treated patients (Chapter 141). The mortality rate associated with hospitalization due to major gastrointestinal events is 5 to 6% in recent studies. Mortality rates associated with upper or lower gastrointestinal complications due to NSAIDs are similar. The major risk factors for upper gastrointestinal bleeding are represented by age and a prior history of gastrointestinal disorders (E-Fig. 36-1). Male gender, cigarette smoking, and heavy alcohol intake increase this risk by less than two-fold, as do oral glucocorticoids. Oral anticoagulants, thienopyridines, and low-dose aspirin increase the risk of NSAID-induced bleeding complications by two- to three-fold. The excess of these complications due to traditional NSAIDs has been estimated to range between 3 and 30 events per 1000 patients treated per year depending on the absence or presence of risk factors (E-Fig. 36-1).

Highly selective COX-2 inhibitors are associated with a statistically significant 50 to 66% relative risk reduction in ulcer complications compared with naproxen or ibuprofen.■ However, no such agent is available on the U.S. market.

A meta-analysis of tabular data from 138 randomized trials of five different coxibs in approximately 145,000 patients has revealed that, in placebo comparisons, allocation to a coxib was associated with a 42% increased incidence of vascular events with no statistically significant heterogeneity among the different coxibs.■ This excess risk of vascular events was derived primarily from a two-fold increased risk of myocardial infarction. Overall, there was no significant difference in the incidence of vascular events between a coxib and any traditional NSAID, but there was evidence of significant heterogeneity between naproxen and the other traditional NSAIDs (largely represented by ibuprofen and diclofenac).■

Current evidence suggests that the risk of myocardial infarction depends on the extent of COX-2 inhibition and not on the variable COX-2 selectivity of the inhibitor. This risk appears to be modulated by concomitant high-grade and persistent inhibition of platelet COX-1 activity, as suggested by the neutral cardiovascular phenotype associated with a high-dose regimen of naproxen. However, in patients at high cardiovascular risk, whose platelet COX-1 is completely and persistently inactivated by low-dose aspirin, the administration of any COX-2 inhibitor (including naproxen) is likely to produce detrimental cardiovascular consequences.

Given the nonlinear relationship between inhibition of platelet COX-1 activity and inhibition of platelet activation in vivo, it is perhaps not surprising that the cardiovascular safety profiles of coxibs and some traditional NSAIDs appear similar because they both fail to inhibit platelet activation adequately irrespective of their COX-2 selectivity. Early appearance, dose dependence, and slow dissipation of risk are important features of COX-2-related cardiotoxicity.

ANTITHROMBOTIC THERAPY

SAM SCHULMAN AND JACK HIRSH

Antithrombotic therapy suppresses the natural hemostatic mechanisms (Chapter 174) and is effective for preventing and treating venous, cardiac, and arterial thromboembolism. A variety of medications are now available that interfere with different steps in coagulation and platelet activation, sometimes with synergistic effects. In recent years, randomized clinical trials have produced a substantial body of evidence-based literature to guide the use of antithrombotic therapy for a wide range of clinical conditions.

PHARMACOLOGIC AGENTS

Vitamin K Antagonists

For more than 60 years, vitamin K antagonists have been the only oral anticoagulants available for clinical use. Now, with the development of novel oral agents that target single coagulation enzymes (see later), the situation is changing. Coumarins are vitamin K antagonists, of which warfarin is the most widely used. Coumarins inhibit a vitamin K reductase that catalyzes the reduction of 2,3-epoxide (vitamin K epoxide), thereby leading to the depletion of vitamin KH_2, which is required for the production of functionally active (γ-carboxylated) coagulation proteins (factors II [prothrombin], VII, IX, and X) and anticoagulant proteins (protein C and protein S) (Chapter 178). Vitamin K_1 in food sources can reverse these effects of coumarins because it is reduced to vitamin KH_2 by a warfarin-insensitive vitamin K reductase (Fig. 37-1).

Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. It has a half-life of about 40 hours, a delayed onset of action (2 to 7 days, depending on dose), and a residual anticoagulant effect for up to 5 days after treatment is discontinued. The dose-response relationship of warfarin varies widely among individuals and is influenced by many factors, including age, body weight, liver disease, dietary vitamin K_1, genetic factors, concomitant drug use, compliance of the patient, and inappropriate dosage adjustments.■ Of these factors, inappropriate dosage adjustment and improved compliance through patient education are the most readily correctable.

The effect of warfarin must be monitored closely to prevent overdosing or underdosing. Laboratory monitoring is performed by measuring the prothrombin time and is reported as an international normalized ratio (INR). During initiation of warfarin therapy, the INR reflects primarily the depression of factor VII, which has a half-life of only 6 hours. There is evidence that the reliability of warfarin monitoring is improved by having the dosage controlled by an anticoagulation management service and by using computer-assisted algorithms. The convenience of monitoring is increased with a portable point-of-care instrument. Pharmacogenetic-guided dosing of warfarin has been evaluated in four randomized trials without producing evidence that the rate of major hemorrhage or thromboembolic complications is reduced, and the current cost is $100 to $200 per patient.

Indications for Warfarin

Warfarin is effective in the primary and secondary prevention of systemic embolism in patients with atrial fibrillation (Chapter 64); in the prevention of systemic arterial embolism in patients with valvular heart disease

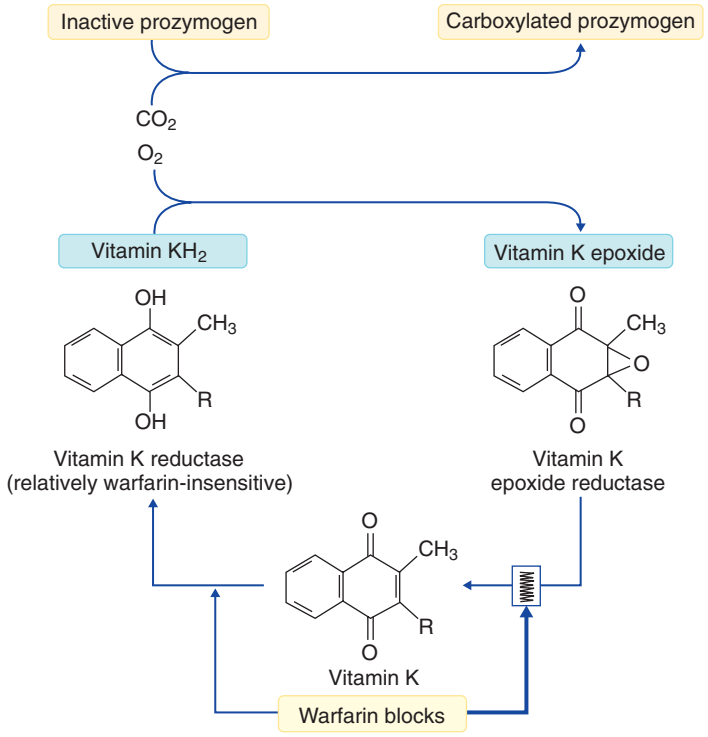

FIGURE 37-1. Warfarin inhibits vitamin K epoxide reductase and leads to the intracellular depletion (in the hepatocyte) of vitamin KH_2. Vitamin KH_2 is required for the conversion (by γ-carboxylation) of functionally inactive to active coagulation proteins. The anticoagulant effect of warfarin can be reversed by vitamin K_1 in food because it is reduced to vitamin KH_2 by a warfarin-insensitive vitamin K reductase.

(bioprosthetic and mechanical heart valves [Chapter 75]); in the primary and secondary prevention of venous thromboembolism (Chapters 81 and 98); in the prevention of acute myocardial infarction in high-risk patients (Chapters 72 and 73); and in the prevention of stroke (Chapter 414), recurrent infarction, and death in patients with acute myocardial infarction (Chapter 73). A target INR of 2.5 (range, 2.0 to 3.0) is recommended for almost all indications. Exceptions are mechanical prosthetic heart valve in the mitral position or caged-ball or caged-disk valve in the aortic position or any mechanical aortic valve in combination with atrial fibrillation, anterior myocardial infarction, left atrial enlargement, or low ejection fraction, when an INR of 3.0 (range, 2.5 to 3.5) is recommended.

Dosing and Monitoring

If a rapid anticoagulant effect is required, heparin and warfarin should be started at the same time and overlapped for at least 5 days. Warfarin is started with the estimated maintenance dose of about 5 mg/day, with the first INR measurement after 2 to 3 days, and patients usually reach an INR of 2.0 in 4 or 5 days. If there is no increase of the INR after two or three doses, the daily dose should be progressively increased until an INR response is observed. In patients with a low risk of bleeding, warfarin may be started at a dose of 10 mg and then adjusted according to daily INR results. Heparin treatment is discontinued when the INR has been in the therapeutic range for 2 days. The INR is then performed two or three times weekly for 1 to 2 weeks and then weekly up to a maximal interval of 4 weeks, depending on the stability of INR results, and more frequently when a new drug is added to the treatment.

Adjustments to the dose when the INR drifts out of the therapeutic range should be gradual and based on the weekly dose (e.g., a 10 to 20% change in weekly dose). Patients should be encouraged to keep a log of their dose and their INR response.

Adverse Effects

Warfarin-related bleeding is increased by the level of the INR. The risk of bleeding is also increased with concomitant aspirin use, in persons older than 65 years, in those with a history of stroke or gastrointestinal bleeding, and in those with serious comorbid conditions. Elderly patients are more sensitive to warfarin, requiring lower doses to reach the therapeutic range, and have an increased tendency to bleed, including intracranially, even when their INR is in the therapeutic range (Chapter 23).

TABLE 37-1 RECOMMENDED MANAGEMENT OF ELEVATED INR WITH OR WITHOUT BLEEDING IN PATIENTS TREATED WITH WARFARIN

INR	BLEEDING	WARFARIN	VITAMIN K_1	FFP/PCC/rFVIIa
<5.0	Negligible	Hold 1 dose or reduce dose	No	No
5.0-9.9	Negligible	Hold 1-2 doses	1-2.5 mg PO*	No
≥10	Negligible	Hold	2.5-5 mg PO	No
Any	Serious or life-threatening	Hold	10 mg IV† and repeat PRN	Yes

*Only for patients at increased risk of bleeding.[26]
†Intravenous (IV) infusion should be given slowly.
FFP = fresh-frozen plasma; INR = International Normalized Ratio; PCC = prothrombin complex concentrate; PO = orally; PRN = as needed; rFVIIa, recombinant factor VIIa.

Warfarin-induced skin necrosis occurs in 1 in 5000 patients, more frequently in women, and affects mainly breasts, buttocks, and thighs. An imbalance between moderately reduced procoagulant factors and severely depressed natural inhibitors may cause this hypercoagulable state in patients with congenital deficiency of protein C or protein S (Chapter 179), dietary deficiency of vitamin K, cancer, or heparin-induced thrombocytopenia with premature start of vitamin K antagonists (Chapter 175).

Reversing the Effect of Warfarin

The anticoagulant effect of warfarin can be reversed in one of three ways: by discontinuation of therapy, with the expectation that the INR will return to baseline in about 5 days; by administration of vitamin K_1, with the expectation that the anticoagulant effect will be reduced in 6 hours and reversed in 24 hours; and by infusion of fresh-frozen plasma (FFP), prothrombin complex concentrate (PCC), or recombinant coagulation factor VIIa (rFVIIa), which produce immediate reversal (Table 37-1).

Heparin and Low-Molecular-Weight Heparins

Heparin

Heparin binds to antithrombin (AT), thereby increasing the rate at which AT inactivates thrombin, activated factor X (factor Xa), and other coagulation enzymes. Heparin accelerates the inactivation of thrombin by AT by providing a template to which both the enzyme and the inhibitor bind to form a ternary complex (Fig. 37-2). In contrast, the inactivation of factor Xa by the AT-heparin complex does not require ternary complex formation and is achieved by binding of the heparin-bound AT to factor Xa. Heparin binds to a number of plasma, platelet, and endothelial cell–derived proteins that compete with AT for heparin binding. Binding of heparin to plasma proteins contributes to the variability of its anticoagulant response, whereas binding to hepatic macrophages is responsible for its dose-dependent clearance. Both properties contribute to the unpredictable anticoagulant effect of heparin and the need for laboratory monitoring.

Heparin is effective for the prevention and treatment of venous thromboembolism,[8-10] for the early treatment of patients with unstable angina and acute myocardial infarction,[11,12] for patients who have cardiac surgery under cardiopulmonary bypass,[13] for patients undergoing vascular surgery,[14] and during and after coronary angioplasty and coronary stent placement.[15]

The anticoagulant effects of heparin are usually monitored by the activated partial thromboplastin time (aPTT). A therapeutic effect is achieved when the aPTT ratio is equivalent to a heparin level of 0.3 to 0.7 anti–factor Xa units, which for many reagents is an aPTT ratio of 1.5 to 2.5.[16] The risk of bleeding complications is increased with increasing heparin dosage, which in turn is related to the anticoagulant response. However, other clinical factors, such as recent surgery, trauma, and invasive procedures, are also important as predictors of bleeding during heparin treatment.

For the treatment of venous thromboembolism, heparin is given in doses of 80 U/kg followed by 18 U/kg per hour by continuous infusion; the dose is adjusted according to the aPTT result at 6 hours by use of a validated nomogram. Lower doses (70 U/kg or 5000 U followed by 15 U/kg/h or 1000 U/hour) of heparin are used in patients with acute myocardial ischemia, who also receive aspirin and platelet glycoprotein IIb/IIIa complex (GPIIb-IIIa) antagonists or thrombolytic therapy.

The main complications of heparin are bleeding and heparin-induced thrombocytopenia. Less common complications are heparin-induced

osteoporosis and hyperkalemia. Heparin-related bleeding is dose related, and the risk is increased in patients who undergo an invasive procedure and if heparin is used in combination with a platelet GPIIb-IIIa antagonist or a thrombolytic agent.

If heparin-induced thrombocytopenia (Chapter 175) is suspected on clinical grounds and anticoagulant treatment is indicated, heparin should be stopped and replaced with a thrombin inhibitor, either hirudin (lepirudin) or argatroban. Warfarin should not be used alone to treat acute heparin-induced thrombocytopenia because it can aggravate the thrombotic process, but it is safe in combination with a thrombin inhibitor after the platelet count has risen above 100×10^9/L.

Low-Molecular-Weight Heparins

LMWHs are fragments produced by either chemical or enzymatic depolymerization of heparin. LMWHs are approximately one third the size of heparin (Table 37-2). Depolymerization of heparin changes the anticoagulant profile. As a result, LMWHs have less protein and cellular binding and, as a consequence, have a more predictable dose response, better bioavailability, and a longer plasma half-life than regular heparin. LMWHs can therefore be administered subcutaneously once daily without laboratory monitoring.

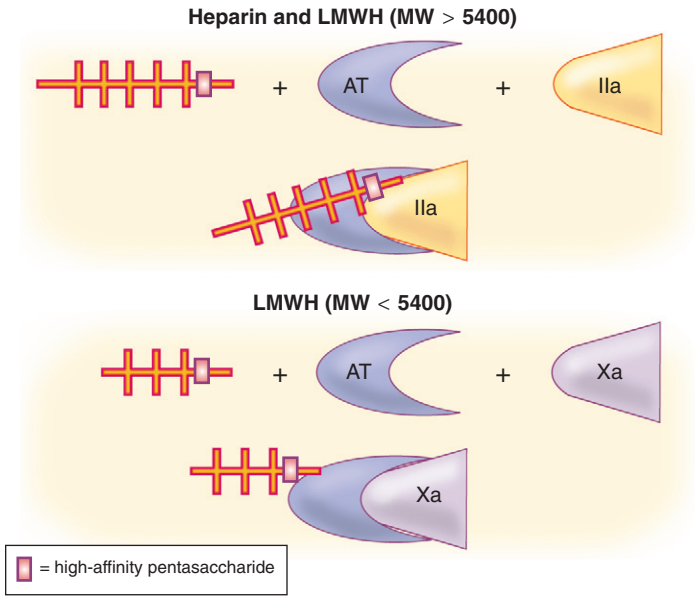

FIGURE 37-2. Only one third of high-affinity pentasaccharide-containing heparin molecules and one fifth of pentasaccharide-containing low-molecular-weight heparin (LMWH) molecules activate antithrombin (AT). Virtually all of the high-affinity heparin molecules are large enough to bridge between AT and factor IIa (thrombin). In contrast, only 25 to 50% of LMWH molecules have a molecular weight (MW) of 5400 or more, and although these smaller molecules inactivate factor Xa, they do not inactivate factor IIa. Although heparin has equal anti–factor IIa and anti–factor Xa activities, LMWH has reduced anti–factor IIa activity.

Compared with heparin, which has a ratio of anti–factor Xa to anti–factor IIa activity of approximately 1:1, the various commercial LMWHs have ratios of anti–factor Xa to anti–factor IIa varying between 4:1 and 2:1, depending on their molecular size distribution. LMWHs are cleared principally by the renal route. LMWHs are associated with a lower incidence of heparin-induced thrombocytopenia and heparin-induced osteoporosis than is heparin.

LMWHs are effective in the prevention and treatment of venous thromboembolism (VTE) (Chapter 81),[1,2] in the treatment of patients with unstable angina and non–ST elevation myocardial infarction (Chapters 72 and 73),[3] and as an adjunct to fibrinolytic therapy in patients with acute ST elevation myocardial infarction (Chapter 73).[4]

Pentasaccharides

On the basis of knowledge of the AT-binding sequence on heparin, a pentasaccharide, fondaparinux, with high affinity for AT has been synthesized. The structure of fondaparinux has been modified to increase its affinity to AT. Fondaparinux inactivates factor Xa through an AT-mediated mechanism. Because it is too short to bridge AT to thrombin, fondaparinux has no activity against thrombin.

After subcutaneous injection, fondaparinux is rapidly and completely absorbed and exhibits a bioavailability of 100%. The volume of distribution is similar to the blood volume. The drug is mainly excreted unchanged in the urine, with a terminal half-life of 17 hours in young volunteers and 21 hours in elderly volunteers.[5]

Fondaparinux circulates extensively bound to AT with minimal binding to other plasma proteins. Limited experimental and clinical studies suggest that fondaparinux has a lower risk of heparin-induced thrombocytopenia than that of heparin or LMWH as well as a lower risk of bone loss and of local skin reactions.

Fondaparinux is effective in the prevention and treatment of VTE[6,7] and is also effective in the treatment of acute coronary syndromes.[8,9]

New Anticoagulants

The limitations of established anticoagulants have prompted the development of a variety of new anticoagulant agents that target various specific steps in the coagulation mechanism.

Direct Thrombin Inhibitors

Direct thrombin inhibitors act independently of AT to inactivate both free thrombin and thrombin bound to fibrin. The direct thrombin inhibitors include hirudin, synthetic hirudin fragments (hirugen, lepirudin, and

TABLE 37-2 ANTICOAGULANT PROFILES, MOLECULAR WEIGHTS, PLASMA HALF-LIVES, AND RECOMMENDED DOSES OF COMMERCIAL LOW-MOLECULAR-WEIGHT HEPARINS

AGENT	ANTI-X_a/ANTI-II_a RATIO	MOLECULAR WEIGHT	PLASMA HALF-LIFE (MIN)	*Recommended Dose (International Anti-Xa Units)* GENERAL SURGERY PROPHYLAXIS	ORTHOPEDIC SURGERY PROPHYLAXIS	ACUTE TREATMENT

Dalteparin	2:1	5000	119-139	2500 U SC daily	2500 U SC bid or 5000 U SC daily	8400 U SC bid*† or 14,000 U SC daily*
Nadroparin	3.2:1	4500	132-162	2850 U SC daily	2700 U SC daily,* 4000 U SC daily* from day 4	13,300 U SC daily*
Tinzaparin (Innohep)	1.9:1	4500	111	3500 U SC daily	3500 U SC daily* or 4500 U SC daily*	12,250 U daily*
Ardeparin	2:1	6000	200		50 U/kg SC bid	
Danaparoid‡	20:1	6500	1100	750 U SC daily	750 U SC bid	2500 U IV, then 4 hr each of 400 U/hr and 300 U/hr, then 200 U/hr; or 2000 U SC bid

*Weight-adjusted dose; stated dose for 70-kg patient.
†The higher daily dose is for acute coronary syndromes; the lower dose is for deep vein thrombosis.
‡Danaparoid sodium is a heparinoid.
IV = intravenously; SC = subcutaneously.

bivalirudin [Hirulog]), and low-molecular-weight inhibitors that react with the active site of thrombin (dabigatran and argatroban).[10]

Bivalirudin is approved for use in coronary angioplasty (Chapter 73),[11] and both argatroban and lepirudin are approved in patients with heparin-induced thrombocytopenia (Chapter 175). Data comparing argatroban with hirudin in heparin-induced thrombocytopenia are too limited for conclusions to be drawn about their relative efficacy and safety. Argatroban is metabolized in the liver and can be used in patients with renal failure, whereas the other direct thrombin inhibitors depend on elimination through renal excretion, and they may be used in patients with liver disease.

Dabigatran etexilate is metabolized by ubiquitous esterases to dabigatran, a reversible, active-site thrombin inhibitor. The bioavailability after oral administration is 6%; the half-life is 12 to 17 hours with substantial prolongation in case of renal failure, owing to predominant elimination through the kidneys. Dabigatran etexilate has been approved in Europe and several other countries for prophylaxis against VTE after hip or knee arthroplasty (first dose, 110 mg; then 220 mg once daily; for patients over 70 years of age or with creatinine clearance, 30 to 50 mL/minute, first dose 75 mg and then 150 mg daily). The effect is similar to that of enoxaparin (40 mg subcutaneously daily).[12] Dabigatran (150 mg twice daily) is more effective than warfarin for stroke prophylaxis in atrial fibrillation, whereas a lower dose (110 mg twice daily) is equally effective with lower risk for major bleeding. Both doses resulted in fewer intracranial hemorrhages than warfarin.[13] Dabigatran has been approved for this use in the United States and Canada. In the treatment of VTE, dabigatran (150 mg twice daily) has comparable effect to warfarin and is at least as safe regarding bleeding.[14]

Direct Factor Xa Inhibitors

A number of orally available low-molecular-weight active site-directed factor Xa inhibitors have been designed and are in various stages of clinical development (rivaroxaban, apixaban, betrixaban, edoxaban). Unlike heparins and pentasaccharides, direct inhibitors inactivate factor Xa without the need for AT as a cofactor.[10]

Rivaroxaban, an oxazolidinone derivative, has a bioavailability of 80%, reaches maximal plasma concentration 1 to 4 hours after oral administration, and has a half-life of 5 to 9 hours in young volunteers and 11 to 13 hours in elderly volunteers. Elimination occurs to one third each through the hepatofecal route, intact through the kidneys, and as a metabolite through the kidneys. Rivaroxaban (10 mg daily for 30-39 days) is more effective than enoxaparin in patients undergoing hip or knee arthroplasty but with a trend to more bleeding.[15]

Apixaban has also a high bioavailability, mixed pathway elimination, and a half-life of 12 hours. Given for prophylaxis against VTE after knee arthroplasty, apixaban (2.5 mg twice daily) has similar or better efficacy than LMWH and similar or lower risk of bleeding.[16,17]

Platelet-Active Drugs

The platelet-active drugs inhibit different steps in either platelet activation (aspirin, ticlopidine, clopidogrel, prasugrel, cilostazol, and dipyridamole) or platelet recruitment (GPIIb-IIIa antagonists abciximab, tirofiban, and eptifibatide) (Fig. 37-3).[10,18]

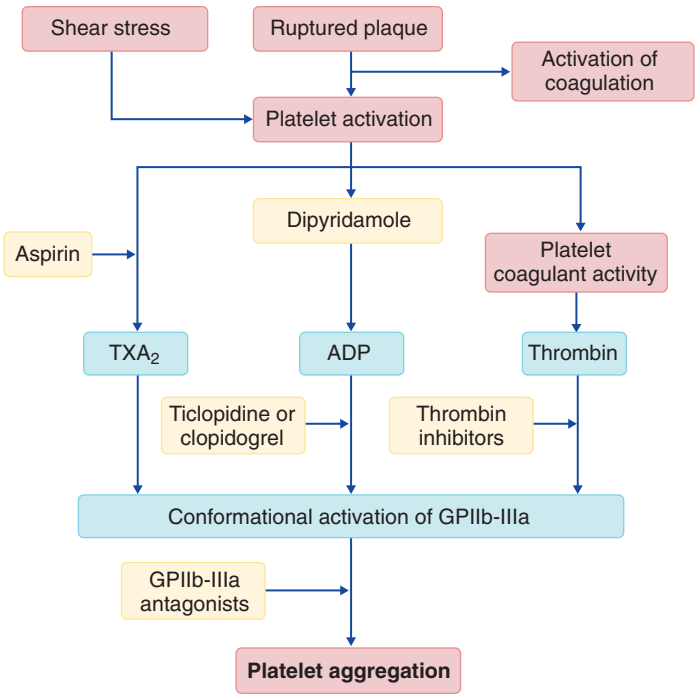

FIGURE 37-3. Sites of action of platelet inhibitors. ADP = adenosine diphosphate; GPIIb-IIIa = glycoprotein IIb/IIIa complex; TXA_2 = thromboxane A_2.

Aspirin and Other Cyclooxygenase Inhibitors

Mechanism of Action and Pharmacology

Aspirin permanently inactivates cyclooxygenase isoenzymes (COX-1 and COX-2) that catalyze the conversion of arachidonic acid to prostaglandin H_2, a precursor of a variety of eicosanoids including thromboxane A_2 in platelets and prostacyclin (prostaglandin I_2) in vascular endothelial cells.

Aspirin is rapidly absorbed in the stomach and upper intestine, attaining peak plasma levels about 30 minutes after ingestion; it has a half-life of about 15 minutes. Inhibition of platelet function is evident by 1 hour with uncoated aspirin but can be delayed after administration of enteric-coated aspirin. Therefore, if only enteric-coated tablets are available when a rapid effect is required, the tablets should be chewed.

Aspirin potentiates the antithrombotic effects of warfarin (in high-risk subjects), dipyridamole (in those with ischemic stroke), clopidogrel (in those with coronary stents or acute myocardial ischemia), and heparin (in the prevention of recurrent miscarriages in pregnant women with antiphospholipid antibody syndrome and in patients with acute coronary ischemia). Aspirin produces a small increase in major bleeding and a very small increase in the risk of cerebral hemorrhage. It also potentiates bleeding when it is added to another antithrombotic agent.

Aspirin causes gastrointestinal side effects that are dose dependent. Aspirin is contraindicated in individuals with active peptic ulcer disease or aspirin-induced asthma or if gastrointestinal side effects are severe.

Clinical Uses

Based on the results of a meta-analysis, there is evidence that aspirin reduces vascular death by approximately 15% and nonfatal vascular events by about 30% in patients with cardiovascular disease (Table 37-3).[18] These effects are achieved in patients with silent myocardial ischemia or stable angina, unstable angina, non–ST elevation myocardial infarction, ST elevation myocardial infarction, and ischemic cerebrovascular disease.[6-8,19] Aspirin is also effective in patients after coronary angioplasty or coronary artery bypass surgery[8] and in preventing symptomatic coronary events in asymptomatic men and women older than 50 years.[8,18] Aspirin has a favorable risk-to-benefit ratio for secondary prevention in patients with overt vascular disease, but the risk-to-benefit ratio is marginal when aspirin is used as primary prevention in asymptomatic individuals, even individuals with type 2 diabetes.[20] Aspirin is less effective than oral anticoagulants in the prevention of recurrent stroke in atrial fibrillation[21] and less effective than LMWH or warfarin in preventing venous thromboembolism.[8]

Phosphodiesterase Inhibitors

Dipyridamole and cilostazol are phosphodiesterase inhibitors, which elevate platelet cyclic adenosine and guanine monophosphate (cAMP and cGMP) levels. They block platelet reactivity and also inhibit vasoconstriction. The most common side effect is headache.

Dipyridamole is a pyrimidopyrimidine derivative with a terminal half-life of 10 hours and elimination primarily by biliary excretion. Favorable results were obtained with a modified-release preparation in patients with prior stroke or transient ischemic attack, in whom the risk of stroke was reduced by 16% with dipyridamole alone and by 37% with aspirin and dipyridamole in combination, compared with placebo.[18,19]

In a meta-analysis, cilostazol (100 mg twice daily) was shown to improve maximal and pain-free walking distance in patients with intermittent claudication.[22] Cilostazol is contraindicated in patients with congestive heart failure, owing to reports of fatal events with similar drugs.

Thienopyridines

Ticlopidine, clopidogrel, and prasugrel are thienopyridines that inhibit adenosine diphosphate–induced platelet aggregation through the action of their active metabolites at the $P2Y_{12}$ receptor level. The drugs are administered

orally, but their onset of action is delayed until their active metabolites are formed. Similarly, recovery of platelet function is delayed until the circulating affected platelets are replaced by newly formed, unaffected platelets.

Based on a better safety profile and equal efficacy, clopidogrel has replaced ticlopidine. Clopidogrel is rapidly absorbed and metabolized, producing inhibition of platelet aggregation as soon as 90 minutes after an oral loading dosing of 300 mg. With repeated daily administration of low doses (75 mg), there is cumulative inhibition of platelet function with a return to normal 7 days after the last dose of clopidogrel.

Clopidogrel is more effective than aspirin in patients who have experienced a recent stroke or recent myocardial infarction and in patients presenting with symptomatic peripheral arterial disease.[5,9,19] The additional benefit over aspirin is modest and similar to that observed with ticlopidine (about 10% relative risk reduction). The combination of clopidogrel and aspirin is also more effective than aspirin alone in patients with unstable angina and non–ST elevation myocardial infarction (20% risk reduction)[63] and in patients with atrial fibrillation,[23] but at a cost of a modest increase in bleeding. The combination of clopidogrel and aspirin is also more effective than

TABLE 37-3 SUMMARY OF GRADE A RECOMMENDATIONS FOR ANTITHROMBOTIC THERAPY

Grade 1A indicates that experts are certain that benefits do or do not outweigh risks, burdens, and costs. Grade 2A indicates that they are less certain, resulting in a weaker recommendation.

PREVENTION OF VENOUS THROMBOEMBOLISM (Chapters 81 and 98)[5]

General Recommendations

Every general hospital should develop a formal, active strategy to prevent venous thromboembolism, such as computer decision support systems (grade 1A).
Patients at high risk for or with active bleeding: mechanical methods—elastic stockings or intermittent pneumatic compression (grade 1A)

General Surgery

Moderate-risk general surgery: LMWH, low-dose unfractionated heparin or fondaparinux (grade 1A)
Higher-risk general surgery: LMWH, low-dose unfractionated heparin or fondaparinux; for major procedures until discharge from hospital (grade 1A)
Major gynecologic surgery for benign disease: LMWH, or low-dose unfractionated heparin every 12 hours (grade 1A)
Extensive gynecologic surgery for malignant disease: low-dose unfractionated heparin every 8 hours, higher doses of LMWH, or intermittent pneumatic compression as long as patient is not ambulating (grade 1A)

Major Orthopedic Surgery

Elective total hip replacement surgery: subcutaneous LMWH, started either 12 hours before or 12-24 hours after surgery or 4-6 hours after surgery at half dose; fondaparinux, started 6-24 hours after surgery; or adjusted-dose warfarin (INR target of 2.5; range, 2.0 to 3.0), started preoperatively or immediately after surgery (grade 1A)
Elective total knee replacement surgery: LMWH, fondaparinux, or adjusted-dose warfarin (grade 1A)
Hip fracture surgery: fondaparinux (grade 1A)
Anticoagulant prophylaxis should be continued for at least 10 days (grade 1A). Extended prophylaxis should be given for up to 35 days with LMWH after total hip replacement and with fondaparinux after hip fracture surgery (grade 1A). Routine duplex ultrasonography screening at the time of hospital discharge or during outpatient follow-up is not recommended in asymptomatic patients after total hip replacement or total knee replacement (grade 1A).
Isolated distal lower-extremity injuries: routine thromboprophylaxis is not recommended (grade 2A)

Neurosurgery, Burns, Trauma, and Acute Spinal Cord Injury

Neurosurgery: intermittent pneumatic compression (grade 1A) or LMWH started after surgery (grade 2A)
Trauma or burn patients: all burn patients with at least one risk factor for VTE and all patients with major trauma or acute spinal cord injury should receive thromboprophylaxis, if it is not contraindicated (grade 1A). LMWH is started as soon as it is considered safe (grade 1A).

Medical Conditions

Acutely ill medical patients, confined to bed and with at least one additional risk factor for VTE: low-dose unfractionated heparin, LMWH or fondaparinux (grade 1A)

Critical Care

Most patients should, after appropriate assessment of the risk for VTE, receive thromboprophylaxis: if medically ill or postoperative—with unfractionated heparin or LMWH; with major trauma or orthopedic surgery—with LMWH (grade 1A).

TREATMENT OF VENOUS THROMBOEMBOLIC DISEASE (Chapters 81 and 98)[5]

Acute Treatment

Acute treatment: LMWH, or unfractionated heparin IV, adjusted dose SC or fixed dose SC, or fondaparinux (grade 1A)
Start treatment with vitamin K antagonists on the first day (grade 1A).
Patients with DVT: early ambulation when feasible (grade 1A)

Long-Term Anticoagulation

Patients with VTE and cancer: treat with LMWH for the first 3-6 months (grade 1A).
Patients with a first episode of VTE and reversible or time-limited risk factors: treat with vitamin K antagonists for 3 months (grade 1A).
Patients with a first episode of unprovoked VTE: treat for at least 3 months and extend long-term if risk factors for bleeding are absent and good anticoagulation monitoring is achievable (grade 1A).
After two or more episodes: treat long-term (grade 1A).
Adjust the dose of vitamin K antagonist to maintain a target INR of 2.5 with a range of 2.0 to 3.0 for all treatment durations (grade 1A). In patients with a strong preference for less frequent INR testing after the first 3 months, continue with INR range 1.5 to 1.9 (grade 1A).
Prescribe an elastic compression stocking with an ankle pressure of 30 to 40 mm Hg for 2 years after a proximal DVT (grade 1A).
Women treated with warfarin after VTE and who become pregnant: substitute with unfractionated heparin or LMWH (grade 1A).
Women using warfarin or unfractionated heparin and who wish to breast-feed: continue the medication (grade 1A).

ATRIAL FIBRILLATION (Chapter 64)[23]

Patients with Previous Ischemic Stroke, TIA, Systemic Embolism, or at Least One Other Risk Factor for Stroke

Standard approach: warfarin anticoagulation (INR of 2.5; range, 2.0 to 3.0) (grade 1A)
Warfarin contraindicated or declined by patient: aspirin, 75 to 325 mg daily
Aspirin plus low-, fixed-dose warfarin should not be used.

VALVULAR AND STRUCTURAL HEART DISEASE (Chapter 75)[27]

Mitral Valve Disease

Rheumatic mitral valve disease with atrial fibrillation, previous systemic embolism, or left atrial thrombus: warfarin anticoagulation (INR of 2.5; range, 2.0 to 3.0) (grade 1A)
Mitral valve prolapse with documented but unexplained TIA: long-term aspirin, 50 to 162 mg daily (grade 1A)

Mechanical Heart Valves

Warfarin anticoagulation (grade 1A)

Patent Foramen Ovale

Patent foramen ovale and stroke: platelet-active drug

ACUTE ST SEGMENT ELEVATION MYOCARDIAL INFARCTION AND CORONARY THROMBOLYSIS (Chapter 73)[63]

All patients with acute myocardial infarction should receive aspirin (160 to 325 mg), chewed and swallowed, at initial evaluation by health care personnel (grade 1A).
Maintenance dose of 75 to 162 mg daily should be continued indefinitely (grade 1A).
All patients should also receive clopidogrel, 300 mg for patients less than 75 years old and 75 mg for older patients without reperfusion therapy, followed by 75 mg daily for up to 28 days (grade 1A).
All patients should also receive anticoagulation (grade 1A), with fondaparinux for patients with no reperfusion therapy (first dose 2.5 mg IV, then SC daily for up to 9 days) (grade 1A), or with enoxaparin for patients with fibrinolytic therapy and preserved renal function (grade 2A).
Anticoagulation should be extended for at least 3 months, using warfarin (INR 2.0 to 3.0), for patients with large anterior myocardial infarction, significant heart failure, intracardiac thrombus, or atrial fibrillation (grade 2A).
Patients with ischemic symptoms characteristic of myocardial infarction of less than 12 hours' duration and persistent ST segment elevation should be rapidly evaluated for reperfusion therapy with primary percutaneous coronary intervention or thrombolysis (grade 1A).
Thrombolytic therapy should be given before arrival to the hospital, when feasible (grade A), and otherwise ideally within 30 minutes from arrival (grade 1A).
Choice of fibrinolytic agent for patients with symptom duration <12 hours: streptokinase, anistreplase, reteplase, tenecteplase, or alteplase (grade 1A).
Choice of fibrinolytic agent for patients with symptom duration <6 hours: alteplase and tenecteplase are superior to streptokinase (grade 1A).

TABLE 37-3 SUMMARY OF GRADE A RECOMMENDATIONS FOR ANTITHROMBOTIC THERAPY—cont'd

NON–ST SEGMENT ELEVATION ACUTE CORONARY SYNDROMES AND PERCUTANEOUS CORONARY INTERVENTIONS (Chapters 72 and 74)[7,8]

Platelet-Active Drugs

Aspirin, non–enteric-coated, at an initial dose of 162 to 325 mg to chew and swallow as soon as possible after the clinical impression of unstable angina is formed (grade 1A). Aspirin by mouth, 75 to 100 mg, should be continued indefinitely (grade 1A).
In cases of aspirin allergy or intolerance: clopidogrel at a bolus dose of 300 mg orally and then 75 mg indefinitely (grade 1A).
Patients at a moderate to high risk for an ischemic event and planned for early invasive strategy: "upstream" clopidogrel (300-mg bolus orally, followed by 75 mg daily) or a GPIIb-IIIa antagonist IV (eptifibatide or tirofiban) (grade 1A) or both (grade 2A).
Clopidogrel should be continued, in addition to aspirin, for 12 months (grade 1A).

Anticoagulants

Unfractionated heparin, LMWH, bivalirudin or fondaparinux (grade 1A). For patients with early conservative strategy: fondaparinux (grade 1A)

CHRONIC CORONARY ARTERY DISEASE (Chapter 71)[9]

Primary Prevention

Moderate or high risk for a coronary event: aspirin, 75 to 100 mg daily (grade 2A)
Very high risk with easily monitored INR: warfarin targeted at INR of approximately 1.5 (grade 2A)

CORONARY ARTERY BYPASS GRAFTS (Chapter 74)[10]

Aspirin, 75 to 100 mg (75 to 162 mg for internal mammary bypass grafting) indefinitely (grade 1A), starting after surgery (grade 2A)
Discontinue clopidogrel 5 days before the operation (grade 2A).

ANTITHROMBOTIC THERAPY IN PATIENTS UNDERGOING PERCUTANEOUS CORONARY INTERVENTION (Chapters 72 and 74)[11]

Platelet-Active Drugs

Aspirin, 162 to 325 mg, should be administered before PCI (grade 1A).
Aspirin, 75 to 100 mg daily, should be used for secondary prevention of cardiovascular events (grade 1A).

Thienopyridines

Clopidogrel should be combined with aspirin for 12 months after bare metal stent placement (grade 1A) and for at least 12 months after drug-eluting stent (grade 1A).

Platelet Glycoprotein IIb/IIIa Antagonists

Abciximab (0.25 mg/kg bolus and 12-hour infusion at 10 μg/min) or eptifibatide (two bolus doses of 180 μg/kg 10 minutes apart) should be considered in all patients undergoing percutaneous coronary intervention, particularly patients with refractory unstable angina or with other high-risk features (grade 1A).

ANTITHROMBOTIC THERAPY IN PERIPHERAL ARTERIAL OCCLUSIVE DISEASE (Chapter 79)[12]

Patients should be treated indefinitely with a platelet-active agent (grade 1A).
Moderate to severe disabling intermittent claudication, not responding to exercise and not candidate for invasive procedures: cilostazol (grade 1A)
Patients with carotid endarterectomy should be treated preoperatively and continued indefinitely with aspirin, 75 to 100 mg daily (grade 1A).
Adding warfarin to aspirin for peripheral arterial disease is not more effective but increases life-threatening bleeding.[13]

Peripheral Vascular Reconstructive Surgery

Patients having infrainguinal bypass operations: aspirin, 75 to 100 mg/day, begun preoperatively (grade 1A)

Intraoperative Anticoagulation Therapy

Patients undergoing major vascular reconstructive operations should be systemically anticoagulated with heparin at the time of application of cross-clamps (grade 1A).

ANTITHROMBOTIC AND THROMBOLYTIC THERAPY FOR ISCHEMIC STROKE (Chapter 414)[14]

Acute ischemic stroke treatment within 3 hours of onset of symptoms:
Thrombolytic therapy: in eligible patients, IV t-PA in a dose of 0.9 mg/kg (maximum of 90 mg), with 10% of the total dose given as an initial bolus and the remainder infused during 60 minutes (grade 1A).
Streptokinase is not recommended (grade 1A).
Acute ischemic stroke patients not receiving thrombolysis:
Aspirin, 150 to 325 mg/day, started early (grade 1A)

DVT or Pulmonary Embolism Prophylaxis

For acute stroke patients with restricted mobility: low-dose subcutaneous heparin or LMWH, provided there are no contraindications to anticoagulation (grade 1A)

Stroke Prevention

Noncardioembolic cerebral ischemic events (stroke or TIA; atherothrombotic, lacunar, or cryptogenic): platelet-active drugs (grade 1A); preferably the combination of aspirin and extended-release dipyridamole (25/200 mg bid) (grade 1A) or otherwise aspirin, 50 to 100 mg/day or clopidogrel (75 mg daily) are acceptable options for initial therapy.
Patients with recent acute coronary syndrome: clopidogrel plus aspirin (75 to 100 mg daily) (grade 1A)
Stroke and aortic atherosclerotic lesions: platelet-active drugs
Cardioembolic ischemic events: long-term warfarin (target INR of 2.5; range, 2.0 to 3.0) for atrial fibrillation (grade 1A)
Carotid endarterectomy: aspirin, 50 to 100 mg/day, before carotid endarterectomy and continued long-term after the procedure

aPTT = activated partial thromboplastin time; DVT = deep vein thrombosis; ECG = electrocardiogram; FFP = fresh-frozen plasma; INR = International Normalized Ratio; IV = intravenous; LMWH = low-molecular-weight heparin; PCC = prothrombin complex concentrate; PCI = percutaneous coronary intervention; rFVIIa = recombinant factor VIIa; SC = subcutaneously; TIA = transient ischemic attack; t-PA = tissue plasminogen activator; VTE = venous thromboembolism.

aspirin alone in patients who have percutaneous coronary intervention procedures. Clopidogrel appears to be as well tolerated as aspirin.[15]

Prasugrel is more potent and has a more rapid onset of action than clopidogrel.[16] Given as a bolus dose of 60 mg, followed by 10 mg daily, when compared with clopidogrel, prasugrel reduces the absolute risk of cardiovascular death or nonfatal myocardial infarction or stroke by 2.2%, which is partly offset by an absolute increase of serious bleeding of 0.5%.[17]

Ticagrelor, an oral direct and reversible $P2Y_{12}$ receptor inhibitor, provides a faster response than the thienopyridines.[18] In a randomized trial in patients with acute coronary syndromes, ticagrelor was more effective than clopidogrel, providing an absolute risk reduction for cardiovascular death, myocardial infarction, or stroke of 1.9% without any significant increase of major bleeding.[19]

Integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) Receptor Antagonists

The final common pathway of platelet aggregation is mediated by the binding of fibrinogen to the functionally active integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) on the platelet surface. Inhibitors of this process include monoclonal antibodies, synthetic peptides containing Arg-Gly-Asp (RGD) or Lys-Gly-Asp (KGD), and peptidomimetic and nonpeptide RGD mimetics. These compounds are administered intravenously and inhibit platelet function by competing with fibrinogen (and von Willebrand factor) for occupancy on the platelet integrin receptor.[20] Abciximab (ReoPro), a mouse-human chimeric 7E3 Fab antibody, inhibits platelet aggregation in a concentration-dependent manner. Platelet function is impaired rapidly after an intravenous bolus of abciximab and gradually recovers over 24 to 48 hours. Tirofiban (MK-383, Aggrastat) is a nonpeptide derivative of tyrosine. It has a plasma half-life of 1.6 hours, and its effect on hemostasis is reversed within 4 hours of stopping treatment. Eptifibatide (Integrilin) is a synthetic disulfide-linked cyclic heptapeptide. It has a rapid onset and offset of action, and its effect on platelet function is reduced by more than 50% after 4 hours.

All three GPIIb-IIIa receptor antagonists are effective intravenous agents in patients undergoing percutaneous coronary interventions[10] (Chapter 74), and tirofiban and eptifibatide are effective in patients with unstable angina or non–ST elevation myocardial infarction.[11] The GPIIb-IIIa receptor antagonists are administered in combination with heparin and aspirin. Orally active nonpeptide GPIIb-IIIa inhibitors have been developed for long-term use, but the results of clinical trials have been disappointing.

Fibrinolytic Agents

Fibrinolytic agents convert plasminogen to the enzyme plasmin, which then degrades fibrin to soluble fragments, thereby lysing the thrombus. Of the available fibrinolytic agents, streptokinase and urokinase are not fibrin specific; in contrast, recombinant tissue-type plasminogen activator (rt-PA, alteplase) and the rt-PA variant tenecteplase are relatively fibrin specific (Chapter 73).

Streptokinase is an indirect fibrinolytic agent. It binds to plasminogen, converting it into a plasmin-like molecule that in turn converts plasminogen to plasmin. Streptokinase has a number of disadvantages. It is antigenic, rendering its repeated use problematic, and allergenic, producing chills, fever, and rigors in some patients and, in rare instances, anaphylaxis. Anistreplase (APSAC) is an acylated complex of streptokinase and Lys-plasminogen. Compared with streptokinase, it is more fibrin specific, has a longer plasma half-life, and is inactive until it is selectively activated by deacylation on the fibrin surface. Its side-effect profile, antigenicity, and efficacy are similar to those of streptokinase.

Urokinase is a naturally occurring plasminogen activator that differs from streptokinase in that it directly activates plasminogen and is not antigenic. Urokinase was used extensively to treat peripheral vascular occlusions, but production problems have curtailed its availability.

In its natural state, tissue plasminogen activator is produced by vascular endothelium; rt-PA (alteplase) is produced by recombinant DNA technology. Alteplase is not antigenic or allergenic, and it has greater fibrin specificity than does streptokinase. It has a short half-life of about 3.5 minutes and therefore is given as a continuous intravenous infusion.

Truncated forms of rt-PA have been developed; the first was reteplase (r-PA), a single-chain deletion mutant that lacks certain domains. As a result, its half-life is about twice that of rt-PA, permitting double-bolus therapy 30 minutes apart. r-PA has lower affinity for fibrin than does rt-PA, but fibrinogen depletion with r-PA is less than that with streptokinase. No antigenicity has been reported with this compound.

Tenecteplase (TNK-tPA) is a mutant tissue plasminogen activator with amino acid substitution at three sites. Compared with rt-PA, it has a longer half-life, allowing single-bolus administration, increased fibrin specificity, and increased resistance to inhibition by plasminogen activator inhibitor 1.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

MARY CHARLSON

COMPLEMENTARY AND INTEGRATIVE INTERVENTIONS

Despite tremendous strides by modern medicine in understanding the mechanisms of disease and improving treatments, many patients faced with illness find that conventional therapies do not completely alleviate their suffering. As a result, many patients, particularly those who have experienced life-threatening illnesses, turn to alternative or complementary therapies that they believe will make them feel better.

Most complementary therapies are provided in community settings, not in health institutions. In 2007 a nationally representative sample showed that almost 40% of adults and 11% of children in the United States had used complementary or alternative medical (CAM) therapies in the prior year. CAM modalities include biologically based therapies, body-based practices, mind-body therapies, energy medicine, and whole medical systems; the proportion of U.S. adults using these CAM modalities in 2007 is shown in Table 38-1. Of note, adults had more visits with CAM practitioners, including acupuncturists, massage therapists, and herbalists, than they had with primary care physicians. Most people who use CAM modalities do not disclose this to their physicians because they are concerned that their physicians may not understand or support the use of such approaches.

The use of CAM modalities is particularly high in cancer patients. Eighty percent of patients who are undergoing treatment for cancer use one or more CAM modalities, and about half tell their oncologists. The use of CAM modalities does not stop when treatment is over; in fact, patients may seek such modalities even more aggressively after treatment is completed, much to the surprise of their physicians. When oncologists tell patients that their treatment is over and that they have an excellent prognosis or that the critical time frame for recurrence has passed, they expect the patients to be enormously relieved. All too often, patients experience distress when told that they can go back to their usual lives, asking, "What life?" The growing field

TABLE 38-2 QUESTIONS PHYSICIANS CAN ASK TO EXPLORE PATIENTS' BELIEFS

What do you think this illness does?
What worries you with this illness?
Why did you think you got this illness?
How do you think it should be treated?
Who do you ask for advice about illness?

of survivorship medicine recognizes that patients who have had cancer may face ongoing physical, psychological, and spiritual challenges.

Most often, patients who are feeling distressed are referred to support groups. Surprisingly, support groups were not shown to improve quality of life in breast cancer survivors in randomized trials. Cognitive-behavioral therapy may also be recommended for patients who experience anxiety after treatment for cancer. Randomized trials have shown that cognitive-behavioral therapy may be effective in improving mood in cancer patients. More and more, cancer survivors reach for complementary or integrative approaches to healing and health to address their psychological, physical, and spiritual needs.

Integrative health is a broad framework that encompasses complex biologic, psychological, cultural, and social pathways to health and disease. *Complementary medicine* encompasses adjunctive approaches to conventional medicine for preventing or treating illness or distress. These alternative approaches are embraced in many different communities and cultures.

THE IMPORTANCE OF PATIENT BELIEFS, EXPECTATIONS, AND CULTURES

Beliefs about illness and health and about the risks and benefits of treatment are deeply rooted at a cultural and social network level. Americans rely on family and social networks for advice about how to handle most illnesses and see physicians for only 10 to 20% of illness episodes. Social networks in many communities help determine many individuals' beliefs and expectations with regard to health and the use of different treatment modalities. Emerging data suggest that apart from determining expectations about disease and treatment, social networks can have a profound impact on health and affect. A recent analysis of the Framingham data showed that obesity spreads through social networks. The chance of becoming obese increased by 171% if a friend became obese or 40% if a sibling became obese. Obesity was not higher in neighbors, suggesting that the findings were not due to environmental confounding. Instead, obesity appears to be propagated through social networks. A similar analysis of the Framingham data suggested that happiness is also spread through social networks. Such social network influences are rarely considered in modern medicine, except in approaches to HIV and drug addiction.

Physicians are often not aware that their patients have beliefs about the cause of their illness (i.e., their explanatory model). As a result, it is common for patient-doctor discussions to involve major discrepancies in understanding, expectations, and goals. For example, Hmong parents in Minnesota who placed heated cups on their children's skin to relieve chest congestion (a traditional practice) were mistakenly reported for child abuse because the cups caused erythematous patches. Puerto Rican women who reported having visions during religious ceremonies (as was expected) were incorrectly diagnosed as having schizophrenia. Understanding and addressing patients' beliefs is critical to overcoming otherwise hidden barriers to adopting effective treatments and preventing unintended consequences. Questions that can be employed to elucidate patients' beliefs are shown in Table 38-2. Explanatory models of illness are deeply rooted in culture and embedded in indigenous medical systems and healing practices.

INDIGENOUS MEDICAL SYSTEMS AND TRADITIONAL HEALING PRACTICES

Having evolved over thousands of years, most indigenous medical systems frame health as balance or harmony and illness as imbalance. To treat illness, indigenous systems seek to restore balance using a combination of foods, herbs, physical manipulation, movement, prayer, and social interventions. Each has its own methods of diagnosis, using the patient's symptoms and often his or her family or social situation.

For Native Americans, health means staying strong in spirit, mind, and body and staying in harmony with oneself, one's community, and the earth. Efforts to restore health focus on healing the spirit of the person who is ill and healing the community and the environment. Ceremonies and rituals such as the sweat lodge as well as herbal remedies may be used. Ayurvedic (ancient Indian) medicine focuses on achieving a balance of three elements—vata (air), pita (bile), and kapha (phlegm)—through the use of foods, herbs, yoga, meditation, and massage. Traditional Chinese medicine draws on ancient theory to achieve a balance of yin and yang (opposites) and the five elements (water, wood, fire, earth, and metal) through acupuncture, herbs, foods, and massage. The life force or energy, called *Qi*, is believed to flow through meridians; acupuncture, tai chi, and qi gong are all thought to balance the flow of energy. Tibetan medicine combines elements from Ayurvedic, Greek, and Chinese medical systems with the Buddhist philosophy that all illness and suffering come from the mind; it emphasizes guided meditation as central to harmony and healing. African traditional medicine frames illness as a physical or mental problem caused by a disruption of a person's own balance or his or her social relationships. Diagnosis involves identifying the spiritual cause of the illness; treatments are designed to restore spiritual and social balance and may involve herbals, prayers to ancestors, and family interventions, as well as rituals and ceremonies. Obviously, these descriptions are too short to do justice to any of these traditions, but they emphasize that each of these indigenous medical systems has specific theories about the cause of, susceptibility to, and treatment for certain conditions and specific strategies for diagnosis. These traditional systems are currently being used to treat millions of people worldwide. In Asia and Africa, the World Health Organization estimates that 80% of people currently depend primarily on traditional medicine.

There is limited research about the effectiveness of indigenous medical systems as a whole because these systems are deeply intertwined with culture. Most Western research has taken one element or tool from a traditional system and tested its use to treat a specific condition or disease. For example, acupuncture has been shown to reduce nausea and vomiting induced by chemotherapy. Iyengar yoga improves function and reduces pain in patients with chronic back pain. Tai chi reduces pain and improves function among patients with osteoarthritis of the knee. Our knowledge is limited about the effectiveness of specific practices across diverse communities; specifically, we do not know whether responses to therapies differ between populations that have used "alternative" approaches for many years as part of their healing traditions and those that have only recently begun to incorporate them.

TRADITIONAL VERSUS MODERN MEDICINE: THE MIND AND THE BODY

In traditional medical systems, the mind and spirit were not viewed as separate from the body; the health of the mind and spirit was viewed as central to physical health. Many traditional systems held that physical illness is caused by disturbances of the mind or spirit. As a result, many interventions were designed to improve the health of the mind and spirit.

In the Indo-Tibetan Buddhist tradition, healing focuses on building the discipline of attention through healing visualization, recitation, and deep breathing. The Tibetans developed a comprehensive system of self-healing and learning called the *gradual path*, which deals with the causes of suffering and the approaches to end suffering. Self-healing is taught through meditation guided by a mentor. Recently, guided meditation in this tradition has been shown to improve quality of life in breast cancer survivors.

African traditional medicine focuses on the spiritual causes of illness and then on the physical manifestations. The traditional healer understands the beliefs and normative values of the community and interprets what the patient has done wrong to cause the illness. The intervention may involve prayer, dancing, singing, drumming, ritual, or community ceremonies. Recently, traditional healers have developed rituals for the rehabilitation of children who were abducted and forced to become soldiers. Reconciliation with their dead ancestors and with those who died is a central part of the ritual. These rituals were adapted from those used for centuries to peacefully reintegrate returning warriors into the community.

Native American healing focuses on restoring health and harmony with the community and with nature. Illness is believed to stem from spiritual imbalances. Purifying and cleansing the body and spirit through sweat lodge ceremonies is an important healing tradition. Other rituals may include the whole community and involve drumming, singing, chanting, and prayers. Sweat lodge rituals have improved the success of interventions designed to change addictive behaviors.

For the most part, Western medicine does not have equivalent approaches. The focus of Western medicine has been medical and surgical treatments for the physical body. Most interventions target the individual patient. Community-based rituals or interventions for improving health are still largely the province of religious institutions. The difference between modern medicine and indigenous systems grew out of the mind-body dichotomy. Introduced by Descartes in the West, the philosophy that the mind and the body are separate and distinct provided the foundation for modern medicine. The physical body became the focus of Western medicine, while the mind and the spirit were exclusively the domain of the church.

THE MIND-BODY CONNECTION

For some time it has been clear that psychosocial states such as stress, social isolation, and depression alter the risk of developing chronic illness and increase the risk of adverse outcomes. For example, depression increases the risk of developing heart disease. Depressive symptoms also increase the risk of morbidity and mortality among patients who have heart disease. Lack of emotional support increases mortality in patients who have had a myocardial infarction. Sudden emotional stress can precipitate heart failure in patients without coronary artery disease.

Psychosocial stress may be caused by a discrete life event such as the death of a family member, chronic situations related to social role or work, or small day-to-day hassles. The impact of a given event depends on how the individual perceives it: is the event a threat, and if so, how severe? An individual's interpretation of events as physical or psychological threats is based on his or her own experience and that of the individual's social network. Once an event is perceived as a potential threat, an individual may experience negative emotions, such as anger or anxiety. Such emotions activate emotional memory and trigger reaction patterns learned in response to prior stresses, initiating the neuroendocrine stress response. People react to stress with their own patterned behavioral responses, and most resultant behaviors tend to increase the negative impact of stress (e.g., eating unhealthy food, gaining weight, smoking, living a sedentary life, not taking medications). The impact of negative psychosocial states on health has been clear for several decades; however, we have recently gained a greater understanding of the potential mechanisms.

How Does Psychosocial Stress Impact Health?

The repeated triggering of the stress cascade can adversely affect multiple aspects of health and adaptation. There is emerging evidence that psychosocial stress is one of the most salient, potentially modifiable mechanisms linking illness and health.

Allostatic Load

An approach has been defined to measure the cumulative toll exacted by adverse behavioral, psychological, social, physiologic, and environmental stressors. Stress causes specific neural and endocrine responses, with sympathetic activation resulting in the release of catecholamines from the adrenal medulla and cortisol from the adrenal cortex. The acute stress response is designed to protect against threats to survival. However, chronic stress, especially psychosocial stress, can have a negative impact on health. Chronic stress interferes with biologic regulatory processes central to homeostasis. Chronic stress disrupts the hypothalamic-pituitary-adrenal (HPA) axis, resulting in abnormal circadian cortisol rhythms, with elevated and flattened diurnal cortisol levels and elevated overnight urinary cortisol. Stress also disrupts the autonomic balance, resulting in an increase in sympathetic versus parasympathetic function and elevated levels of urinary catecholamines. There are multiple biologic markers of the stress response that indicate cumulative stress-related wear and tear, which is called *allostatic load*. The potential adverse consequences of allostatic load were evaluated in the MacArthur Studies of Successful Aging, which followed 736 healthy men and women between 70 and 79 years of age. Among patients without cardiovascular disease at baseline, patients with a higher allostatic load had a higher mortality and greater functional decline that those with a lower allostatic load. Of note, older men with more social network ties and greater social integration had lower allostatic load scores. Therefore, individuals under chronic stress had greater neuroendocrine and cardiovascular responses and subsequent adverse health outcomes.

Stress Reactivity

Efforts to measure sympathetic-parasympathetic balance have focused on measures of stress reactivity, including heart rate variability and blood pressure. Studies measuring cardiovascular reactivity in the context of daily life have yielded valuable insights. For example, day-to-day social interactions may be associated with changes in cardiovascular reactivity; the changes depend on the relationships involved. Negative social relationships may cause activation of the sympathetic nervous system, leading to increased cardiovascular reactivity. People who have increased reactivity to stress have a larger, longer-lasting increase in negative affect. In contrast, during positive social interaction with one's partner, blood pressure levels are lower than during interactions with other people.

In some studies, the health impact of heightened cardiovascular reactivity depended on socioeconomic status. Thus, social context and social support may alter stress reactivity. Increased cardiovascular reactivity to stressors may predict cardiovascular disease.

Chronic work stress has significant health consequences. The Whitehall study showed that workers with higher chronic work-related stress had a higher incidence of coronary heart disease and higher death rates from heart disease. Higher work stress was associated with four components of the metabolic syndrome (higher fasting glucose, higher triglycerides, greater waist circumference, and lower high-density lipoprotein cholesterol), as well as worse health behaviors (lower physical activity, poor diet) and the development of obesity.

Importantly, higher work stress was also associated with lower heart rate variability. Lower heart rate variability indicates lower vagal tone—that is, reduced parasympathetic and increased sympathetic activity. Lower heart rate variability predicts increased all-cause mortality and increased risk of coronary heart disease. There is a correlation between heart rate variability (the high-frequency component reflecting vagal activity) and emotion-specific changes in blood flow in the medial prefrontal cortex.

The Cholinergic Inflammatory Pathway

The vagus nerve, which controls parasympathetic tone and heart rate variability, also mediates the release of pro- and anti-inflammatory cytokines. Through the vagus nerve, the nervous system has the ability to sense and suppress inflammation through the cholinergic anti-inflammatory pathway. Stimulation of the vagus nerve leads to the release of acetylcholine, which in turn inhibits the inflammatory response by inhibiting the release of pro-inflammatory cytokines (interleukin-6 and tumor necrosis factor). When pro-inflammatory cytokines are released to defend against pathogens, the release is a rapid and localized reflex; however, if pro-inflammatory cytokines are released over a prolonged period, they can create a systemic humoral response, leading to or exacerbating diseases such as rheumatoid arthritis, inflammatory bowel disease, and atherosclerosis.

Stress and the Brain

A large body of literature highlights the effects of chronic stress on the structure and function of the hippocampus and amygdala. The hippocampus is important for both contextual and declarative memory. Severe stress and elevated steroid levels impair memory reversibly and may affect the reliability of contextual memories, which are important in evaluating a potential threat. High levels of stress hormones also impair declarative memory reversibly. Chronic stress can cause a reduction in the size of the hippocampus (which provides negative feedback to the HPA axis). However, there is some evidence of plasticity at least in the dentate gyrus in the hippocampus: in primates, new cells are increased by exercise and enriched environments. A study showed that older patients who are socially disengaged experience cognitive decline, leading to speculation that social engagement may buffer against stress-related damage to the hippocampus.

The amygdala and the prefrontal cortex are also involved in the affective and attentional response to stress. The amygdala is important to threat recognition and fear, as well as emotional learning. Chronic stress causes increases in the amygdala (which provides positive feedback to the HPA axis). The prefrontal cortex likely exerts a major inhibitory influence on the amygdala. Chronic stress interferes with the prefrontal cortex and results in decreased working memory and impaired problem solving. It has been shown that among medical students experiencing the same examination stress, those with higher perceived stress levels also had more impairment in attentional control compared with those whose perceived stress levels were lower. Importantly, after 1 month of vacation, the impairment in prefrontal cortex function was reversible. Thus, stress results in both reversible and irreversible changes in the hippocampus, amygdala, and prefrontal cortex that are involved in multiple aspects of cognition, attention, and emotion.

Stress and Telomere Length

Chronic stress is also associated with telomere length, a marker of cellular age. When telomeres shorten sufficiently, the cell becomes senescent. An important study evaluated mothers of healthy children versus mothers of chronically ill children; the hypothesis was that mothers of ill children would have greater perceived stress than mothers of healthy children and thus shorter telomeres. Instead, the investigators found no difference in telomere length, telomerase activity, or oxidative stress. However, in both groups of mothers, telomere length was correlated with perceived stress; specifically, the higher the mother's perceived stress, the shorter her telomeres were. High-stress mothers had the equivalent of 1 decade of aging in telomere length in contrast to the low-stress mothers. Because the study was cross-sectional, it could not establish whether the correlation represented causation.

Thus, if the stress response, which is designed to protect against acute events, becomes a chronic response, it can have an adverse impact on cellular aging and multiple aspects of regulatory systems, including the HPA axis, parasympathetic-sympathetic tone, the vagus nerve, and the central nervous system.

How Do Integrative Interventions Reduce the Impact of Stress?

Reducing the impact of stress is likely a key mechanism through which many integrative interventions work. It is important to realize that it is not the actual magnitude of the stressor that has the adverse health impact; it is the individual's perception of the stressor. Thus, in two mothers with chronically ill children, telomeres are shortened in the mother with high perceived stress but not in the mother with a low level of perceived stress. Medical students with high levels of perceived stress about an upcoming examination have attentional shifts and impairment in prefrontal cortex function, whereas those with low perceived stress do not.

Integrative interventions are almost uniformly designed to increase confidence in one's own control and in one's ability to self-regulate emotion and mood. Many of these interventions focus on the individual's being present in the moment and achieving nonjudgmental awareness. They are also designed, using different theories, to create greater harmony between the mind and the body.

Cognitive neuroscience has begun to understand meditation as a discipline of attention; stress reduction is achieved through learning. This model is consistent with the view of traditional medical systems that use meditation, prayer, guided imagery, recitation, singing, drumming, and chanting to build present awareness, attention, and harmony. Yoga, tai chi, and qi gong are examples of practices that involve movement and meditation.

Studies of clinically stressed populations indicate that interventions aimed at reducing stress by promoting the cognitive regulation of attention and affective behavior yield enhancements in neuroendocrine and immune function and clinically significant improvements in quality of life. A few small studies have reported changes in heart rate variability in response to an intervention. Transcendental meditation[1] and biofeedback can increase heart rate variability in cardiac patients; acupuncture may also increase heart rate variability. It has been suggested that interventions designed to increase heart rate variability should target patients whose conditions are associated with high levels of pro-inflammatory cytokines, such as inflammatory bowel disease or rheumatoid arthritis. Meditation may also improve blood pressure and insulin resistance.[1] With regard to brain plasticity and telomere shortening, studies have only begun to evaluate interventions' potential to effect changes.

WHY DO PATIENTS SEEK INTEGRATIVE INTERVENTIONS?

First, patients want to play an active role in their recovery and return to health—that is, self-healing. Self-healing is a concept that may seem strange to physicians, yet we know that self-healing (i.e., regeneration) allows repair to occur after injury.

Patient empowerment and active engagement are major determinants of health outcomes. An overwhelming body of literature has shown that confidence in one's ability to do something—that is, self-efficacy—is a powerful predictor of success. More and more studies have shown the importance of whether patients believe they can influence their own health outcomes. People who think they can influence their own outcomes (those with an internal locus of control) fare better than those who believe that what they do does not matter (those with an external locus of control). Of note, it has been known for more than 20 years that locus of control can predict health outcomes and behaviors. Ten-year-olds who believed they could influence events by their own actions had a reduced risk of obesity and psychological distress than those with a greater external locus of control.

Self-efficacy can be enhanced; that is, patients can learn strategies to increase confidence in their ability to cope with illness and thereby improve their health outcomes, at least over the short term.[2] A self-management course, including action planning, modeling of behaviors, problem solving, and a decision-making model, may increase self-efficacy and reduce hospitalizations. Many disease management courses cite this model but miss the critical ingredients of improving self-efficacy, decision making, and problem solving, focusing instead on specific things the patient should monitor and report to the nurse or doctor, potentially undermining self-efficacy and reinforcing the external locus of control.

To date, only a few complementary approaches have achieved widespread use in medical centers. Among commonly used complementary and alternative medical therapies, acupuncture is beneficial for tension-type headache[3]; can improve nausea, vomiting, and other symptoms in cancer patients[4]; can lower blood pressure by about 5.4/2.0 mm Hg during treatment but not after it is stopped[5]; has some benefit for chronic lower back pain,[6] but has small and probably not clinically relevant benefits for peripheral joint osteoarthritis.[7] Tai Chi may be an effective treatment for fibromyalgia.[8] By comparison, Echinacea is not effective for the common cold,[9] hypnotherapy is not effective for smoking cessations,[10] and glucosamine and chondroitin are not beneficial for osteoarthritis of the hip or knee.[11]

PRINCIPLES OF GENETICS

BRUCE R. KORF

The elucidation of the structure and function of the genome is one of the great scientific triumphs of the 20th century. The relevance of inheritance to health and disease probably has been recognized throughout history, but it is only during the last century that the rules governing inheritance and the mechanisms whereby genetic information is stored and used have come to light. The application of this knowledge to medical practice so far has focused on relatively rare monogenic and chromosomal disorders. Major contributions have been made in these areas in the form of approaches to genetic counseling, genetic testing, prenatal diagnosis, newborn screening, carrier screening, and, to a limited extent, treatment. As important as these contributions are, however, their impact has been limited by the rarity of these disorders. Powerful tools resulting from the Human Genome Project are changing this situation (Chapter 42). Genetic factors that contribute to common and rare disorders are being identified, leading to new approaches to diagnosis, prevention, and treatment. Genetics and genomics are increasingly occupying center stage in medical practice, guiding treatment decisions and preventive strategies. This chapter reviews the paradigm whereby genetics is being integrated into the routine practice of medicine.

GENETIC CONTRIBUTION TO DISEASE

It may be argued that no disorder is either completely determined genetically or completely determined by nongenetic factors. Even monogenic conditions, such as phenylketonuria, are modified by the environment, in this case by dietary intake of phenylalanine. Genetically determined host factors are known to modify susceptibility to infection or other environmental agents. Even individuals who are victims of trauma may find themselves at risk in part because of genetic traits that affect behavior or ability to perceive or escape from danger.

Multifactorial Inheritance

Complex traits that are important for both health and disease are the result of an interaction of multiple genes with one another and with the environment (Fig. 39-1). In some cases, individual genes or environmental factors contribute overwhelmingly to the cause of a disorder, as with a genetic condition, such as neurofibromatosis or Marfan syndrome, or an acquired disorder, such as bacterial infection or trauma. Other times, there may be interplay among many factors, making it difficult to dissect out the specific genes or environmental exposures.

From a medical perspective, it is helpful to divide the genetic contribution to disease into three categories: high-penetrance monogenic or chromosomal disorders, monogenic versions of common disorders, and complex, multifactorial disorders. Each of these has an impact on medical practice in distinctive ways.

High-Penetrance Monogenic or Chromosomal Disorders

High-penetrance monogenic or chromosomal disorders are the disorders that most clinicians think of as "genetic conditions." They include rare but familiar single-gene disorders, such as neurofibromatosis, Marfan syndrome, and cystic fibrosis, and chromosomal abnormalities, such as trisomy 21 (Down syndrome). Several thousand distinct human genetic disorders have been described and cataloged in *Mendelian Inheritance in Man* (available at www.ncbi.nlm.nih.gov/Omim/). These include mendelian dominant or recessive disorders, sex-linked disorders, and conditions that are due to mutations within the 16.6-kilobase mitochondrial genome. They also include major chromosomal aneuploidy syndromes and syndromes associated with duplication or deletion of small regions of the genome that result in either reproducible syndromes, such as Williams syndrome (deletion of contiguous loci from a region of chromosome 7), or nonspecific mental retardation.

Role of the Nonspecialist

Because of the rarity of many of these conditions, most practitioners have limited experience with a given disorder and are likely to need to refer the patient to an appropriate specialist for assistance with diagnosis and management. Nevertheless, the nonspecialist has many distinct roles in the care of these patients. These roles begin with the recognition of the fact that the patient may have a disorder and arrangement for appropriate diagnostic evaluation. Many genetic disorders produce obvious signs or symptoms that at least prompt referral even if they are not immediately suggestive of a diagnosis. Others can be more subtle, with nevertheless significant consequences if the diagnosis is missed. An example is Marfan syndrome (Chapter 268). The physician needs to be alert to the physical characteristics of patients with Marfan syndrome because life-threatening aortic dissection can be avoided with appropriate monitoring and treatment. Table 39-1 lists examples of some adult-onset monogenic conditions with which the internist should be familiar.

Treatment of Patients with Genetic Disorders

The treatment of patients with genetic disorders may require the assistance of a specialist, but the nonspecialist is likely to be the first contact when an affected individual is ill. The primary care physician needs to be familiar with the disorder and major potential complications. For example, the patient with neurofibromatosis who experiences chronic back pain may be presenting with a malignant peripheral nerve sheath tumor, requiring more aggressive evaluation than would be typical for an unaffected individual with back pain. Formation of a good working relationship between the specialist and nonspecialist is crucial to ensure effective care.

The nonspecialist also has an important role in supporting the patient and helping to explain the difficult choices that may be offered for management. This includes providing support for patients who have disorders that cannot be treated and for the emotional impact that accompanies knowledge that a disorder may be transmitted to one's offspring or shared with other relatives. Most patients have little understanding of the mechanisms of genetics and genetic disease. Although the responsibility to explain these issues may reside with specialists and counselors, the primary care provider has an important supportive role.

Advances in Genetics

Many of the disorders in this group have been known for a long time, but more recent advances in genetics have had a substantial impact on approaches to diagnosis and management. Genetic testing has been refined with the advent of molecular diagnostic tests that detect mutations within individual genes. Even rare disorders may be amenable to diagnostic testing; a database of testing laboratories can be found on the Internet (available at www.genetests.org). Whole-genome scanning for small deletions or duplications is revealing mutations in patients with disorders such autism, for which standard chromosomal analysis had previously been unrevealing. Population screening for carrier status of some disorders now is offered routinely. Some tests are targeted to particular ethnic groups, such as Ashkenazi Jews (Tay-Sachs disease, Canavan disease, cystic fibrosis, Gaucher's disease) or individuals of African, Mediterranean, or Asian ancestry (hemoglobinopathies) (Table 39-2). Pan-ethnic screening is now being made available for cystic fibrosis, although risks differ in different ethnic groups. Newborn screening is being expanded beyond inborn errors of metabolism such as phenylketonuria and galactosemia, with the advent of tandem mass spectrometry and the availability of a standardized panel of tests. Finally, treatment of some monogenic disorders is becoming feasible. Life expectancy for patients with cystic fibrosis has been increasing gradually with better treatments for chronic lung disease; dietary therapy is available for many inborn errors of metabolism; novel therapies that use either pharmaceuticals or gene or enzyme replacement strategies are in use or being tested for many conditions. The principles of management of genetic disorders are evolving rapidly so that care of patients increasingly requires active partnership of specialists and primary care providers. Moreover, individuals with congenital disorders such as Down syndrome are routinely surviving to adulthood and require primary care providers who are familiar with their special needs.

Monogenic Versions of Common Disorders

Not all monogenic disorders produce obscure phenotypes, and not all common disorders are due to complex multifactorial causes. Some common disorders occur in some families as single-gene traits (Table 39-3). This is usually true for only a proportion of affected individuals, but in some cases it is a significant proportion and represents an important group of patients to be recognized.

Breast Cancer

An example is breast cancer (Chapter 204). About 10% of cases of this common form of cancer can be attributed to mutation in one of two genes, *BRCA1* or *BRCA2*. Women who inherit a mutation in one of these genes face a high risk of eventually developing breast or ovarian cancer—more than 80% by age 70 years for breast cancer. Women at risk because of mutation do not look different from women with sporadic breast cancer but can be distinguished by many features, including family history of breast or ovarian cancer in multiple relatives, early age at onset of cancer, and multifocality of the cancer (e.g., bilateral breast cancer or breast and ovarian cancer).

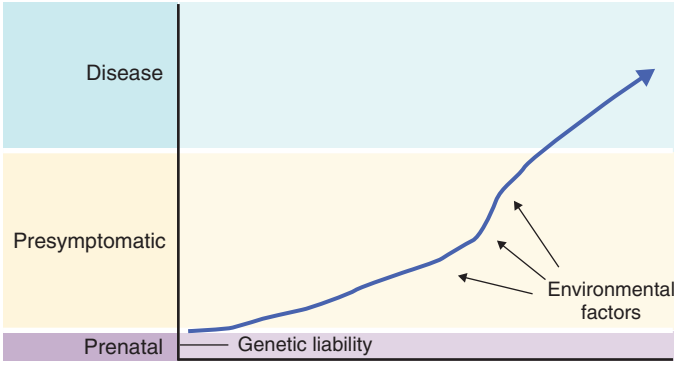

FIGURE 39-1. Multifactorial etiology of disease. An individual is born with a genetic liability but remains in a presymptomatic state for some time until additional events occur, including exposure to environmental factors, that result in crossing a threshold that is identified as *disease*. In instances of high-penetrance monogenic disorders, the genetic liability may be overwhelming. In other instances, genetic factors may contribute only slightly to disease risk.

TABLE 39-1 HIGH-PENETRANCE SINGLE-GENE DISORDERS THAT MAY PRESENT IN ADULTHOOD, WITH SOME MAJOR MEDICAL IMPLICATIONS*

DISORDER	INHERITANCE	MAJOR MEDICAL IMPLICATIONS
CARDIOVASCULAR		
Marfan syndrome	AD	Risk of aortic dissection; lens dislocation
Long QT syndrome	AD, AR	Arrhythmia, sudden death
RENAL		
Adult polycystic kidney disease	AD	Renal failure
PULMONARY		
α_1-Antitrypsin deficiency	AR	Emphysema, cirrhosis
NEUROLOGIC		
NF1	AD	Benign and malignant nerve sheath tumors, gliomas
NF2	AD	Schwannomas (especially vestibular), meningiomas
Von Hippel-Lindau	AD	Hemangioblastoma of cerebellum, brain stem, eye; pheochromocytoma; renal cell carcinoma
Huntington disease	AD	Movement disorder, psychiatric disorder, dementia
HEMATOLOGIC		
Globin disorders	AR	Stroke, iron overload
ENDOCRINE		
MEN syndromes	AD	Tumors of thyroid and parathyroid, pheochromocytoma

*See Table 39-3 for examples of lower penetrance disorders.
AD = autosomal dominant; AR = autosomal recessive; MEN = multiple endocrine neoplasia; NF = neurofibromatosis.

Colon Cancer and Other Common Disorders

Another example from cancer genetics is colon cancer (Chapter 199). Two syndromes, familial adenomatous polyposis and hereditary nonpolyposis colon cancer, are autosomal dominantly inherited and convey a high risk of colon cancer. Other noncancer examples are hemochromatosis (Chapter 219), in which cirrhosis, cardiomyopathy, diabetes, joint disease, and other problems ensue from excessive iron absorption; 10% of whites carry an allele that predisposes to this recessive disorder. Mutations in the factor V gene or the prothrombin gene occur commonly and predispose to deep venous thrombosis (Chapter 179). Rarer examples include inherited forms of cardiomyopathy, hypertension, and familial hypercholesterolemia.

Management

The physician may be called on to address these disorders in many ways. There is a compelling reason to make an early diagnosis of hemochromatosis because the complications can be prevented, but not reversed, by phlebotomy and subsequent monitoring of iron stores. Individuals at risk of colon cancer can be offered surveillance with colonoscopy or surgical resection of the colon to reduce the risk of cancer. Individuals at risk of breast and ovarian cancer likewise can be offered surveillance, chemoprevention, or surgery. The benefits of knowledge of genetic risks are less clear in some instances. Carriers of the factor V Leiden mutation would not be treated with anticoagulation until after an event of thrombosis, and the treatment may not be different for a carrier versus a noncarrier. In some cases, however, knowledge of carrier status might help ensure prompt diagnosis or avoid situations of high risk.

TABLE 39-2 MAJOR RECESSIVE DISORDERS FOR WHICH CARRIER SCREENING COMMONLY IS OFFERED IN THE UNITED STATES

DISORDER	MAJOR AT-RISK POPULATION	CARRIER FREQUENCY
Cystic fibrosis	White Ashkenazi Jewish	1:25 1:29
Sickle cell anemia	African American	1:10
β-Thalassemia	Mediterranean	1:30
α-Thalassemia	Southeast Asian, Chinese	1:30
Tay-Sachs disease	Ashkenazi Jewish French Canadian	1:30 1:30
Canavan's disease	Ashkenazi Jewish	1:40
Familial dysautonomia	Ashkenazi Jewish	1:30

TABLE 39-3 SINGLE-GENE DISORDERS WITH INCOMPLETE PENETRANCE THAT MAY ACCOUNT FOR INHERITED FORMS OF SELECTED COMMON DISORDERS

DISORDER	INHERITANCE: GENES	MAJOR MEDICAL IMPLICATIONS
Hemochromatosis	AR: *HFE*	Cirrhosis, cardiomyopathy, diabetes mellitus
Thrombophilia	AD, AR: multiple genes	Deep venous thrombosis
Breast and ovarian cancers	AD: *BRCA1, BRCA2*	Breast and ovarian cancers
Familial adenomatous polyposis	AD: *APC*	Multiple colonic polyps, colon cancer
Hereditary nonpolyposis colorectal cancer	AD: DNA mismatch repair genes	Colorectal cancer, endometrial cancer
Maturity-onset diabetes of the young	AD: multiple genes	Diabetes mellitus
Cardiomyopathy	AD: genes involved in cardiac contractile apparatus	Arrhythmia, heart failure

AD = autosomal dominant; AR = autosomal recessive.

Genetic Testing

As with other medical tests, the physician should carefully consider risks, benefits, and clinical utility in deciding to use a genetic test. Some distinct ethical and legal risks may apply to some genetic tests. These may include anxiety, stigmatization, guilt, and possibly discrimination for insurance or employment. Some of these risks may be addressed by legislation to maintain privacy of genetic information, such as the Genetic Information Nondiscrimination Act, but the risks of anxiety, guilt, and stigmatization cannot be legislated away. To some extent, further research may improve the basis for surveillance or lead to effective treatments. For now, many of these disorders present a double-edged sword of potentially useful knowledge and potentially harmful information.

Role of the Physician

The role of the physician in dealing with monogenic disorders includes recognition of individuals at risk and participation in formulation of a care plan. Individuals at risk cannot be identified by physical appearance and usually are not evident from medical history or physical examination findings. The most valuable screening tool is the family history. Directed questioning about a family history of major monogenic disorders, especially breast, ovarian, and colon cancer, as well as hypercholesterolemia, hypertension, deep venous thrombosis, cirrhosis, and diabetes, can identify the occasional patient with mendelian segregation of these common disorders. Even if the information is of uncertain reliability, eliciting a family history can prompt referral for further evaluation, documentation of the family history, and consideration for genetic testing. The physician's job is not simply to identify individuals at risk; some people believe they are at high risk even in the absence of well-documented risk factors. Addressing these misconceptions can bring peace of mind and usually does not require genetic testing.

Complex, Multifactorial Disorders

Understanding the genetics of common disorders is one of the great challenges of modern medicine, with the promise of major returns in terms of prevention, diagnosis, and treatment. The etiology of these disorders is complex in that they result from an interaction of multiple genes with one another and with environmental factors. The specific genes that are relevant may be different from one person to the next. Identification of these genes is difficult given this heterogeneity and the relatively small impact that any particular gene may have in a particular person.

Population Studies

Dissection of the genetic contribution to common disease cannot be accomplished by the standard genetic approaches involving study of rare variants or family-based linkage studies. Most recent efforts have focused on study of large groups of patients, comparing the prevalence of particular genetic markers in case patients and control subjects. The availability of markers has been boosted by the identification of single-nucleotide polymorphisms (SNPs) (Chapter 42). These are differences in single DNA bases between individuals that occur every several hundred bases. Some of these account for common genetic differences between people, including differences that may contribute to disease. The catalog of SNPs currently includes several million variants; it has been found that the genome has evolved as blocks of clusters of genes, making it possible to use only a limited number of SNPs within a given region to determine whether there is a gene in that region that is associated with a disease. Since completion of the HapMap Project, there has been a dramatic increase in the number of SNPs found to be associated with common disorders. As genetic risk factors for common disorders come to light, it is likely that there will be advances in risk assessment, disease stratification, and developing new approaches to treatment.

Genetic Risk Assessment

The goal of genetic risk assessment is the identification of individuals at risk of disease before the onset of signs or symptoms. In principle, the genetic factors could be identified at birth, or any time in life, by testing a DNA sample. Individuals found to be at risk might be offered treatment in advance of onset of the disease to avoid complications or might be advised to modify their lifestyle to avoid exposure to environmental factors that might increase their risk of disease. Several companies have begun to offer "personalized genomic testing." Tests are usually accessed through an Internet site without intervention of a health professional and involve analysis of hundreds of thousands of SNPs in a clinical laboratory. Results are provided through a secure Internet site, sometimes with an option for genetic counseling.

Although the concept of genomic risk assessment would appear to be an attractive paradigm, many questions may be raised about its practicality and implementation. First, predictive testing is useful only insofar as it guides further management. This is likely to be a moving target because ability to test for risk can be developed more quickly than ability to modify that risk. The utility of interventions may be valued differently by different people. This already has been the case for testing of disorders such as breast cancer. Some women at risk choose not to know their *BRCA* status because the options, including surveillance or prophylactic surgery, are unacceptable to them. If there were a low-cost, safe, and effective treatment that would neutralize any risk the decision to test would be simple, but short of that, there are reasonable arguments on both sides of the issue of whether to test. For many disorders, it will take a long time to show the efficacy of any intervention because there may be a period of many years between the test and the onset of a disorder. Unless surrogate markers can be identified and followed, the task of proving a benefit to predictive testing may require years to decades in some instances.

Predictive Value of Genetic Testing

A second issue surrounds the degree to which genetic testing would be predictive. Most genetic tests are likely to involve detection of relatively common polymorphic alleles that account for small increments of relative risk of disease. The predictive value of these tests would be modest, perhaps too low to induce an individual to modify behavior or to take medication. Here, again, much depends on the efficacy of any intervention that can be offered. There may be some disorders for which testing would have substantial predictive value and clinical utility and others for which testing would not be justified.

Social and Ethical Issues

A third concern relates to social and ethical issues. Will people use test results as an excuse to pursue self-destructive behaviors, having received what may be false reassurance of "immunity"? Will genetic testing further exacerbate the divide between individuals who can afford to pay for their care and those who cannot? Will people misinterpret results of testing in terms of a simplistic notion of genetic determinism, erroneously believing that their futures have been written, leaving them no recourse but to meet their fate? The rapid pace of technologic change is going to challenge the ability of the social and legal systems to keep pace.

Service Models

Finally, there are questions of the ideal context in which to offer such testing. The personal genomics companies provide their services directly to the consumer in most cases. This creates the obvious risk for incorrect interpretation of results by the patient, although it is not clear that the health care work force is otherwise prepared to deal with the challenges of interpretation of genome-wide studies. The challenges will only increase if whole-genome sequencing at modest cost (e.g., <$1,000) becomes available, as is widely anticipated.

Disease Stratification

A second application of genomics in medical practice entails stratification of disease. Even if genetic testing is not used to predict individuals at risk, it may well be used to determine the most appropriate treatment for a clinically diagnosed disorder. Most common disorders, such as hypertension and diabetes, are symptom complexes that probably result from a variety of causes. The particular combination of causes may differ in different individuals and may respond to different types of treatments. Choice of antihypertensive drug may come to depend on genetic testing to determine the specific cause of hypertension in a patient. There are already examples of genotypes that predict response to drugs, for example, in lung cancer. It is possible that genetic tests eventually will accompany many if not most treatment decisions.

Effects and Identification of Drugs

Aside from helping to choose the most efficacious drug, genetic testing may play a role in avoidance of side effects and in appropriate dosing. Many drugs are known to be associated with rare side effects, some of which are sufficiently severe as to lead the drug to be withdrawn from use. Some of these side effects may occur only in individuals who are susceptible on the basis of having a particular allele at a polymorphic locus. An example is the

TABLE 39-4 GENES IN WHICH COMMON POLYMORPHISMS AFFECT RATES OF DRUG METABOLISM OR ACTION

GENE	MEDICATIONS (EXAMPLES)
CYP2C9	Phenytoin, warfarin
CYP2D6	Debrisoquin, β-blockers, antidepressants
VKORC1	Warfarin
UGT1A1	Irinotecan
Thiopurine methyltransferase	Mercaptopurine, azathioprine
N-acetyltransferase	Isoniazid, hydralazine
CYP2C19	Clopidogrel

association of polymorphisms in certain sodium or potassium channel genes with risk of arrhythmia on exposure to specific drugs.

Absorption and metabolism of drugs are largely under genetic control. Several polymorphisms are known to lead to particularly rapid or slow metabolism, accounting for individuals who experience dose-related side effects or lack of efficacy at standard dosages (Table 39-4). Detection of these polymorphisms would allow customization of drug dosage to an individual's pattern of metabolism, increasing the likelihood of efficacy without a prolonged period of trial-and-error dosing. There has been a major interest in applying this paradigm to warfarin dosing, although questions remain about the cost-effectiveness and practicality of genetic testing in routine use of this drug.

The greatest gift of genetics and genomics to medicine may be in the ability to identify new drug targets and develop new approaches to treatment. Identification of genes that contribute to common disorders is revealing the cellular mechanisms that lead to disease. This knowledge offers the opportunity to develop new pharmaceutical agents that would target the physiologic mechanisms more precisely, leading to drugs that work better and cause fewer side effects. New approaches to gene replacement or insertion of genes into cells as localized drug delivery systems also may be developed. The treatment of common disorders likely would entail the use of approaches developed as a result of genomics even in cases in which genetic testing is not used to predict individuals who are at risk.

CONCLUSION

The Human Genome Project began after most practicing physicians completed their medical training, and few are familiar with the methods and approaches of medical genetics and genomics. Nevertheless, physicians will be using the products of the genome project increasingly in their day-to-day practice during the coming years. Whether they are providing care for a patient with a rare genetic disorder or for a patient with a common condition not usually regarded as genetic, management choices increasingly will be informed by tests and treatments that in some way are based on information from the genome sequence.

The essence of the encounter between a physician and a patient can be distilled to two questions: Why this person? Why this time? A person who seeks medical care is doing so as the product of human evolution, having an ancestry associated with certain genetic vulnerabilities, because of inheritance of certain familial risk factors, because of exposure to some environmental factors, because of a particular physiologic process gone awry, because of behavioral traits that lead the person to seek medical care, because of prompting by family or friends to go to the doctor, because society makes medical services available, and because the person can afford to seek care. Genetics cannot answer all of these questions, but it is providing the key to addressing many of the biologic questions that underlie the medical mysteries that have puzzled humankind for generations.

GENE, GENOMIC, AND CHROMOSOMAL DISORDERS

PAWEŁ STANKIEWICZ AND JAMES R. LUPSKI

THE HUMAN GENOME

Unprecedented technologic advances in molecular biology during the past two decades have enabled the determination of the entire DNA (deoxyribonucleic acid) sequence content of the human genome (Human Genome Project, HGP; *www.ornl.gov/sci/techresources/Human_Genome/home.shtml*) and establishment of a reference haploid genome. To date, a few other personal diploid human genomes have been sequenced, and the enormous amount of available DNA sequence data has expanded our view of the genetic bases of disease.

Human genomic DNA is packaged within the nucleus in 23 chromosome pairs, 22 autosomes, and two sex chromosomes, XX in females and XY in males. The diploid genome (2n) in each cell consists of two identical haploid copies of about 3×10^9 base pairs (bp), thus equaling in total 6 billion nucleotides. Most of the human genome consists of repetitive elements: tandem repeats (e.g., satellite sequences in centromeres), telomeric repeats, microsatellites, minisatellites, and short and long interspersed retrotransposable elements (e.g., *Alu* elements and LINE elements, respectively) (Table 40-1). These elements form heterochromatin; however, their functional role remains largely unknown. The unique DNA sequences constituting euchromatin compose the minority of our genome and include 20,000 to 25,000 genes, 700 micro-RNA genes, pseudogenes, gene fragments, nongenic sequences, and regulatory elements. Although protein coding sequences occupy only about 2% of the human genome, it has been demonstrated recently that the majority of our DNA may be transcribed into RNA.

Approximately 4 to 5% of the human genome, including both repetitive and unique sequences, is present in two or more copies in the haploid genome. DNA fragments larger than 1 kb in size and of DNA sequence identity greater than 90% have been termed *low-copy repeats* (LCRs) or segmental duplications (SDs). Most LCRs have arisen during primate speciation. A subset of LCRs with DNA sequence identity greater than 95 to 97% and longer than 10 kb can lead to local genome instability during both meiotic (constitutional) and mitotic (somatic) cell divisions, resulting in genomic rearrangements.

GENE

The concept of a gene can be traced back to 1865 when Gregor Mendel observed the inheritance of phenotypic traits in the garden pea, *Pisum sativum*. Mendel noted that two *factors*, which we now know to be corresponding DNA loci (alleles) located on homologous chromosomes, separate from each other during meiosis and segregate to two different gametes. This phenomenon of independent segregation is now known as *Mendel's First Law*. *Mendel's Second Law* described the independent segregation of two different (nonallelic) loci during gamete formation. The *inheritance factors* or *units of heredity* encoding the genetic information were later defined as *genes*. We now define *gene* as a fragment of DNA that carries the information used to transcribe it into a functional RNA (ribonucleic acid).

The DNA double helix is composed of four nucleotides: two purine bases, adenine (A) and guanine (G), and two pyrimidine bases, thymine (T) and cytosine (C), all connected to deoxyribose sugars and linked by phosphodiester bonds at the 5′ and 3′ carbons of the sugar (in RNA, thymine is replaced by uracil, U). Three consecutive nucleotides (triplet codon) of the coding DNA encode an amino acid. There are 64 possible different codons (4^3 combinations) but only 20 amino acids; therefore, the genetic code has been termed *degenerate*. Most of the genes in our genome comprise several coding

TABLE 40-1 STRUCTURE OF THE HUMAN GENOME

CHROMATIN FEATURE	SEQUENCE TYPE	HUMAN GENOME (HAPLOID)	SIZE (% OF 3 MILLION BASE PAIRS)*
Euchromatin	Protein coding	20,000-25,000 genes	~2
	Noncoding	RNA genes	
		Regulatory elements	
		Pseudogenes	~38
		Gene fragments	
		Conserved sequences

		DNA transposons	~3

*Estimated.
LTR = Long-terminal repeat.

regions or exons that are separated by noncoding introns. The entire gene (exons and introns) is transcribed into messenger RNA (mRNA) by RNA polymerase II starting from its 5′ end and continuing beyond the polyA recognition signal at the 3′ end. Typically, mRNA begins with a cap and terminates with a polyadenylated (polyA) tail at the 3′ end. In the subsequent process of splicing, the intervening noncoding introns are deleted, and the spliced, mature mRNA is translated into a polypeptide. The polypeptides start at the 5′ end (NH_2) with a methionine encoded by the AUG triplet. At the 3′ end (COOH), the polypeptides are terminated by one of three termination codons: UAA, UAG, or UGA (Fig. 40-1).

Micro-RNAs are single-stranded, 21- to 24-bp RNA molecules encoded by their own genes or introns of other genes but not translated into protein (i.e., they are noncoding RNAs). Micro-RNAs are thought to regulate (usually downregulate) gene expression of more than half of all human protein-coding genes. The phenotypic consequences of micro-RNAs are mainly unknown; they are believed to prevent the development of cancer and other diseases.

GENETIC VARIATION

In addition to the HGP, the International HapMap (*http://hapmap.ncbi.nlm.nih.gov*), Human Genome Diversity (*www.stanford.edu/group/morrinst/hgdp.html*), ENCODE (*www.genome.gov/10005107*), and ongoing personal genome sequencing projects have revealed the tremendous and underappreciated extent of variation in our genome. Genetic variation consists of two major types: (1) nucleotide sequence changes, or single nucleotide variation (SNV), and (2) genome structural changes, or copy-number variation (CNV) (Fig. 40-2).

Single Nucleotide Variation

A genetic polymorphism is defined as a heterozygous DNA variation present in greater than 1% of the population. Genome-wide nucleotide variation has been uncovered in the early phase of DNA sequencing analyses, which showed that human genomes differ mainly by single nucleotide changes. These differences have been termed *single nucleotide polymorphisms* (SNPs) and defined as a nucleotide change at a given position generated by substitution (usually there are two alleles per SNP). Only a minority of SNPs map to exons; however, SNPs located outside of the protein-coding regions can still exert phenotypic effects, such as by modifying gene regulatory elements or transcription factor binding sites, generating splicing mutations, or affecting noncoding RNAs. Any two humans differ on average by about 3.5 million SNVs or SNPs, about 0.1% of the 3.0×10^9 reference haploid genome (phase 3 of the International HapMap project).

A set of consecutive SNPs (or other markers) is defined as a *haplotype*. A nonrandom association of markers in a population not interrupted by meiotic recombination (*crossing-over*) is described as *linkage disequilibrium*. (Note that linkage disequilibrium exemplifies the exception to Mendel's Second Law.)

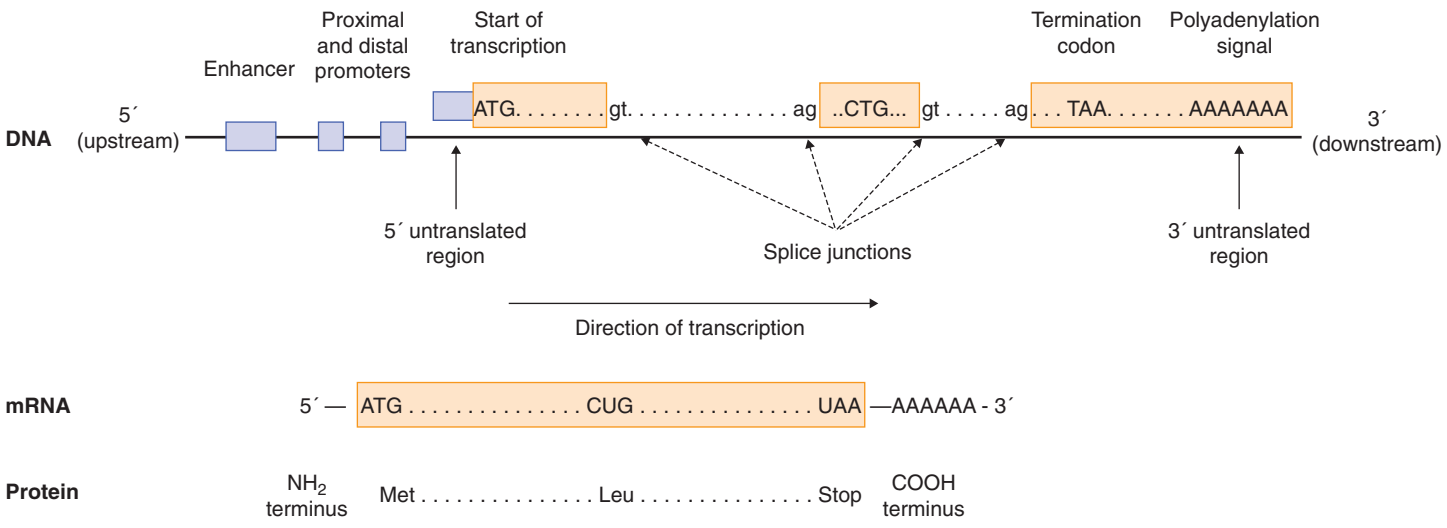

FIGURE 40-1. Gene structure. Schematic representation of the general structure of a typical human gene. Three exons are depicted as *orange open rectangles*. Note that the transcription usually starts with an ATG triplet encoding methionine. The 5′ (upstream) portion of a gene corresponds to the NH_2 terminus, and the 3′ (downstream) segment encodes the COOH terminus of the polypeptide. Enhancers and promoters are shown as *blue rectangles*.

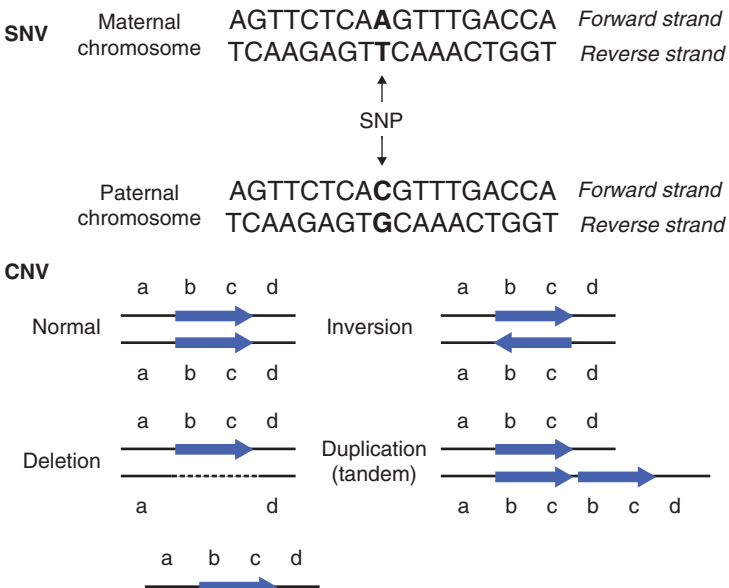

FIGURE 40-2. Genetic variation. *Top,* Heterozygous single nucleotide polymorphism (SNP, or single nucleotide variation SNV) representing the most common transition C→T is shown. *Bottom,* Structural genomic changes: a balanced inversion and the unbalanced copy-number variations (CNVs), deletion, duplication, and amplification are shown with *black arrows* on two homologous chromosomes (*black lines*). The *dashed line* represents a deleted fragment of one chromosome.

Tandem Repeats

Variable number of tandem repeats (VNTRs), or *minisatellites*, and short tandem repeats (STRs) such as unstable dinucleotides, trinucleotides, and tetranucleotides, $(GT)_n$, $(CAA)_n$, or $(GATA)_n$, referred to as *microsatellites*, are highly variable. Both minisatellites and microsatellites have been successfully used in linkage and association studies that enable the mapping of traits and the identification of genes and loci responsible for both mendelian disorders and complex traits. These highly polymorphic sequence repeats are extremely variable in the copy number of their repeating subunits; this property enables the use of a number of such markers to derive a unique pattern of marker genotypes for each human individual. Thus, such markers have been useful for identity testing and DNA forensics.

Repetitive Elements

The other group of polymorphic elements in the human genome is represented by retrotransposons, long and short interspersed nuclear elements (LINEs and SINEs) (see Table 40-1). The most common *Alu* and L1 elements introduce recombinogenic genomic instability and insertional mutagenic activity; their positions within an individual human personal diploid genome can vary tremendously.

Copy-Number Variation

A more recently characterized group of major polymorphic genetic variation in the human genome is represented by structural changes. In this postgenomic era, high-resolution genome-wide analysis of human genome sequences has revealed higher-order architectural features, with a potential to cause genomic instability and extensive submicroscopic structural variations. These structural variations consist of unbalanced CNVs, including deletions, duplications, triplications, insertions, and translocations, that differ from the normal diploid state, as well as balanced rearrangements, such as genomic inversions. Both CNVs and SNVs have been shown to play a major role in human genetic diversity, evolution, and susceptibility to diseases. Surprisingly, it has been found that any two human genomes contain more base pair differences due to CNVs than SNVs.

Recent analyses have revealed over 38,000 CNVs (greater than 100 bp) that occupy more than 29% of the reference human genome. A validated subset of these CNVs overlaps 13% of the Reference Sequence (*www.ncbi.nlm.nih.gov/projects/RefSeq/RSG*) genes and 12% of the Online Mendelian Inheritance in Man (OMIM) (*www.ncbi.nlm.nih.gov/sites/entrez?db=omim*) genes and was predicted by conceptual translation to alter the structure of 12.5% gene transcripts and 5.5% mRNAs. Despite all these recent achievements, the total number, position, size, gene content, and population distribution of CNVs remain obscure because we still do not have accurate and reliable molecular methods to study smaller CNVs on a genome-wide scale in different populations, particularly when copy-number changes are greater than 4 or 5.

CNVs have been shown to be responsible for mendelian diseases, nonmendelian traits such as complex diseases, and common traits (including neurobehavioral traits) or to represent benign polymorphic variation. CNVs can lead to an abnormal phenotype by disrupting the gene structure or changing the copy number of dosage-sensitive genes. However, long-range effects of CNVs involving nongenic sequences, leaving a gene intact, have been also demonstrated. Furthermore, evidence suggests that a combination of two or more CNVs at the same or different loci may be responsible for phenotypic variation. The genome-wide scale of phenotypic effects exerted by CNVs (genomic load) are unknown and await further studies.

Any two individuals differ by about 1000 CNVs ranging in size from about 500 bp to 1 Mb. An updated summary of CNVs can be found in the Toronto Database of Genomic Variants (*http://projects.tcag.ca/variation*). Many clinically relevant CNVs can be found in the Database of Chromosomal Imbalance and Phenotype in Humans using Ensembl Resources (DECIPHER) (*https://decipher.sanger.ac.uk/information*).

CHROMOSOMES

The recombined haploid (1n) human genome formed during meiosis is stored as chromosomes in female and male gametes. They merge at conception, and this diploid genome instructs the development of a zygote; the diploid human genome is subsequently transmitted to the mitotically dividing daughter cells. Human chromosomes can be distinguished from each other in a light microscope by differences in size and characteristic banding patterns after specific chemical staining (e.g., G-banding with Giemsa) when the chromosomes are arrested in a condensed phase (metaphase) of mitotic divisions.

Each human metaphase chromosome is composed of two chromatids that form short (p) and long (q) arms connected by a centromere built with α-satellite DNA. Based on the relative position of the centromere along the chromosome, chromosomes have been described as metacentric (similarly sized p and q arms), submetacentric (q arm significantly longer than p), and acrocentric (chromosomes 13, 14, 15, 21, and 22, with centromeres located close to the end of a chromosome) (Fig. 40-3).

Telomeres consist of repetitive DNA sequences (thousands of copies of TTAGGG repeats) located at the ends of both chromosome arms that are stabilized by a reverse transcriptase enzyme, telomerase, which adds TTAGGG sequence to the 3′ end of DNA strands. In contrast to germline and cancer cells, human somatic cells lacking telomerase gradually lose the telomeric sequences. As a result, cells reach the limit of their replicative capacity and fall into senescence.

Chromosomal Aberrations

Numerical Aberrations

Microscopically visible chromosomal aberrations have been divided into numerical and structural aberrations and are found in 1 in about 160 live births. The numerical aberrations are usually lethal. Polyploidies (multiplication of a haploid set of 23 chromosomes), such as triploidies (3n), 69,XXX, 69,XXY, and 69,XYY, and tetraploidies (4n), 92,XXYY or 92,XXXX, are caused by abnormal egg fertilization by two sperms or by a failure in zygote division, respectively.

The most commonly detected viable chromosomal aneuploidies, trisomies and monosomies, involve chromosomes X, Y, 21, 18, and 13 and arise as a result of meiotic nondisjunctions. Sex chromosome aneuploidies are more common and are found in 1 in 440 newborns. Monosomy X (45,X cell line) in female patients with Turner's syndrome is identified in every 4000 female newborns. However, this birth rate represents only 1% of all fetuses with 45,X because more than 99% are spontaneously aborted (this is similar to the most frequent fetal aneuploidy, trisomy 16, that results in 100% miscarriages). In most cases, the 45,X cell line is found as a mosaic along with another cell line that has either a normal karyotype or a structural rearrangement of the X chromosome (e.g., deletion of the short arm, ring chromosome, or isochromosome of the long or short arms). One in every 1000 males has a 47,XXY chromosome complement that is responsible for Klinefelter's syndrome.

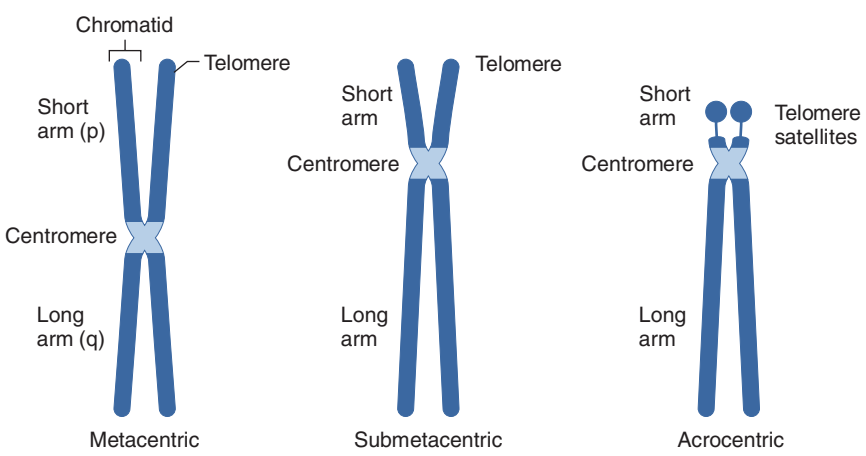

FIGURE 40-3. Types of metaphase chromosomes. Metacentric, submetacentric, and acrocentric chromosomes are composed of two arms connected by a centromere. Each chromosome arm consists of two chromatids.

In contrast to gonosomes, monosomies of all autosomes are lethal. The only trisomies compatible with life are found in patients with Down syndrome (trisomy 21 in every 670 newborns), Edwards' syndrome (trisomy 18 in 1 in 5000 newborns), and Patau's syndrome (trisomy 13 in every 10,000 newborns).

Incomplete supernumerary chromosomes are termed *marker chromosomes*. They usually originate from acrocentric autosomes (~ 50% from chromosome 15) and are found in every 4000 newborns. The severity of the abnormal phenotype in carriers of marker chromosomes varies among different chromosomes and is estimated as 28% in de novo cases.

Structural Aberrations

Chromosomal deletions and duplications have been categorized as microscopically visible or submicroscopic, terminal or interstitial, recurrent or nonrecurrent. The most frequent are recurrent common-sized rearrangements flanked by directly oriented LCRs or SDs that mediate nonallelic homologous recombination (NAHR). For example, an about 3 Mb microdeletion in chromosome 22q11.2 occurs in patients with DiGeorge velocardiofacial syndrome and is found in 1:4000 newborns. The 1.4-Mb Charcot-Marie-Tooth disease type 1A (CMT1A) duplication causes greater than half of all adult-onset inherited Charcot-Marie-Tooth neuropathy, and de novo events account for up to 90% of sporadic cases. The phenotypic consequences of deletion/duplication CNVs depend on whether the CNVs harbor a dosage-sensitive (e.g., haploinsufficient for deletion) gene.

Balanced reciprocal translocations result from an exchange of the DNA material between two chromosomes and are found in 1 in about 600 individuals. During meiosis, the translocation chromosomes form a pachytene tetrad structure and, depending on the segregation type (alternate or adjacent, symmetric or asymmetric), either balanced or unbalanced products are transmitted to progeny. The unbalanced products often lead to either spontaneous abortions or births of clinically affected children. Recently, it has been shown by high-resolution genome analyses that up to 40% of apparently balanced translocations found in subjects with abnormal phenotypes are associated with additional imbalances at or near the translocation breakpoint or somewhere else in the genome.

Translocations involving short arms (or centromeres) of acrocentric chromosomes are described as robertsonian translocations. Balanced robertsonian translocations (45-chromosome complement) are present in 1 in 900 newborns; thus, these are the most common chromosome rearrangements in humans. The most frequent robertsonian translocation, t(13;14), is found in 1 in 1300 individuals. The carriers of balanced robertsonian translocations have a significantly increased risk for an unbalanced karyotype in progeny (e.g., trisomy 21 or trisomy 13) or uniparental disomy for chromosomes 14 and 15 that are known to contain imprinted genes.

Constitutional nonrobertsonian chromosomal translocations are nonrecurrent, with the exception of five recurrent translocations: t(11;22)(q11.2;q23.3) and t(8;22)(q24.13;q11.21), that use AT-rich cruciforms, and translocations t(4;8)(p16;p23), t(8;12)(p23.1p13.31), and t(4;11)(p16;p15.2) that are mediated by LCR gene clusters.

When a fragment of one chromosome is translocated into another chromosome's arm, the aberration is termed an *insertion* or *insertional translocation*. Insertional translocations have been recently shown by high-resolution human genome analyses to occur more than 100 times more frequently than recognized previously. The carrier of a balanced insertion has up to a 50% chance of an unbalanced offspring.

An inversion is defined when a chromosome fragment is reversed end to end. Inversions harboring the centromere are termed *pericentric,* and those with breakpoints mapping in the same chromosome arm are termed *paracentric*. Usually, only the products of pericentric inversions (unbalanced terminal deletion of one chromosome arm accompanied by a terminal duplication of the second arm) are found in a progeny. The acentric or dicentric products of paracentric inversions are unstable and thus not transmitted.

Other, less common structural chromosomal abnormalities include ring chromosomes, isochromosomes, complex chromosome rearrangements, and heterochromatin variants. Rings arise when two broken ends of the same chromosome fuse. Usually, chromosome material telomeric to the breakpoints is lost and leads to an abnormal phenotype. Rings are commonly unstable mitotically and often form double ring structures. Isochromosomes arise when one part of the chromosome is duplicated and separated from the other. Isochromosomes can be monocentric (breakpoint in the centromere) or dicentric and thus unstable, unless one of the centromeres becomes inactivated (pseudoisodicentric). Chromosome aberrations with more than two breakpoints on two or more chromosomes are termed *complex chromosome rearrangements* and often result in an unbalanced product of meiotic division.

Mosaicism and Chimeras

The presence of two or more cell lines with different chromosome complements in one individual is termed *mosaicism* when they originate from the same zygote or *chimeras* when the cells originate from different zygotes. Chromosomal mosaicism is a common phenomenon, observed in about 50% of embryos at the eight-cell stage and in up to 75% of blastocysts. Somatic chromosomal mosaicism is found, for example, in patients with hypomelanosis of Ito and Pallister-Killian syndrome (tetrasomy 12p).

MUTATION

Mutation is defined as a change in nucleotide sequence due to errors of DNA replication, recombination, or repair or to radiation, chemical mutagens, viruses, or transposons. Gene mutations can be inherited from a parent (hereditary, germline, or constitutional) and thus present in every cell. Alternatively, mutations can be acquired in some tissues at some time either during an individual's development or at any time throughout a person's life (somatic) (Fig. 40-4). Recent whole genome sequencing of lung cancer tissue suggests one new point mutation for every pack of cigarettes smoked. Point mutations, usually involving only one or a few nucleotides, have been divided into substitutions, insertions, and deletions. Mutations mapping in protein-coding sequences and changing the protein structure have been termed *nonsynonymous,* whereas those that do not lead to protein change are known as *synonymous* or silent mutations. The latter mutations can still have functional consequences (e.g., by generating a cryptic splice site, an exon splice enhancer, or affecting the regulatory elements).

Based on the functional consequences, mutations have been divided into loss-of-function and gain-of-function mutations. The former, also known as *hypomorphic* (partial loss) or *amorphic* or *null* (complete *loss*), affect the dosage-sensitive or haploinsufficient genes, in which a decreased amount of protein is not sufficient for normal function. Gain-of-function mutations

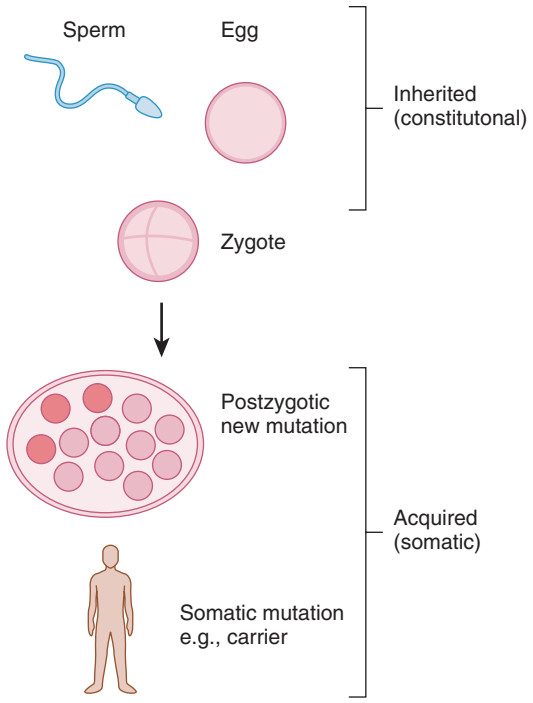

FIGURE 40-4. Mutation. Constitutional mutations are inherited from one of the parents. They can be present in the somatic cells of a parent (carrier) or can arise during gametogenesis (de novo). Mutations that occur postzygotically (acquired, somatic) are usually found in a mosaic state.

increase or add a new function for the protein (*neomorphic*), and dominant negative mutations are translated into a protein that interacts antagonistically with the normal product from the other allele (*antimorphic*).

The situation in which one allele is mutated and the second is normal (wild-type) is referred to as *heterozygous*. A combination of the same two mutations in each of the alleles of the same locus (e.g., in consanguineous families) is defined as *homozygous* mutations, or compound heterozygotes when the two mutant alleles are distinct. Two mutant alleles at different loci are described as *double heterozygote*. When one of the autosomal alleles is absent (e.g., because of a deletion CNV and for most of the X chromosome genes in males), the locus is referred to as *hemizygous*.

Different mutations in one gene can manifest with the same or distinct phenotypes, phenomena called *allelic heterogeneity* or *allelic affinity*, respectively. By contrast, the same abnormal clinical phenotype can be caused by mutations in different genes (genetic or locus heterogeneity).

Single Nucleotide Variation

Nonsynonymous mutations can lead to a single amino acid change (*missense*), modify the downstream protein structure (*frameshift*), introduce a stop codon (*premature termination codon [PTC]*) that truncates the protein prematurely (*nonsense*), or abolish the specific site at which splicing of an intron takes place during the processing of precursor mRNA into mature mRNA (*splice site*). The PTC-mutated mRNAs are inactivated and removed from cells by a surveillance mechanism called *nonsense mediated decay* that is initiated by a premature termination codon in any exon, except the last and a 50- to 55-bp portion of the second to last (i.e., penultimate) exon that usually escape nonsense mediated decay.

Transition mutations refer to changes from pyrimidine to pyrimidine (e.g., C to T) or purine to purine (e.g., A to G), and are more frequent than exchanges from purine to pyrimidine (e.g., A to C) or pyrimidine to purine (e.g., T to G), that is, transversions. The most common C-to-T transition (about ten-fold relative to other bases) occurs in the methylated CpG dinucleotide because methylated C is subject to deamination and becomes T.

Mutations that are unstable have been termed *dynamic*. Pathogenic dynamic expansion of trinucleotide, tetranucleotide, and pentanucleotide repeat sequences can be located in coding (e.g., CAG triplet in Huntington's disease) or noncoding regions such as introns (e.g., GAA in Friedreich's ataxia) or untranslated regions, either 5′ (e.g., CGG in fragile X syndrome, OMIM 300624) or 3′ (e.g., CTG in myotonic dystrophy). The mutations convey phenotypes that can be inherited as autosomal dominant (e.g., myotonic dystrophy), autosomal recessive (e.g., Friedreich's ataxia), or X-linked (e.g., fragile X syndrome) traits due to gain- or loss-of-function mutations. For each of the dynamic mutation diseases, there is a specific repeat number limit, above which the disease is manifested. The number of repeats below that threshold but greater than in normals is referred to as a *premutation*. However, in some "disease genes," premutations are also associated with a milder, nonspecific phenotype (e.g., ovarian failure in females and late-onset neurologic disorders in males with premutations in the fragile X *FMR1* gene). The number of repeats tends to expand in the next generations, a phenomenon called *anticipation*; this typically occurs in a sex-specific manner.

Copy-Number Variation

It has now become apparent that the Watson-Crick DNA base pair changes are not the only mutational mechanism responsible for mendelian monogenic diseases and complex traits. Higher-order genomic architectural features can lead to a regional instability and susceptibility to DNA rearrangements or CNVs, which can be a frequent cause of diseases in humans. Such conditions due to structural genome changes or CNV have been referred to as *genomic disorders*.

A major mechanism by which rearrangements convey phenotypes is gene dosage due to a variation in gene copy number. CNVs can lead to deletion, duplication, or disruption of the dosage-sensitive gene, generate gene fusions, exert position effects, or unmask mutations in the coding region or other functional SNPs in the second allele, as when a deletion CNV results in a hemizygous state.

Different calculations have shown that the de novo locus-specific mutation rates for genomic rearrangements are between 10^{-4} and 10^{-5}, at least 1000 to 10,000 fold more frequent than de novo point mutations. Thus, new mutation CNV can contribute significantly to sporadic disease.

Many genomic disorders occur sporadically and are often caused by de novo rearrangements. Recurrent rearrangements (deletions, duplications, or inversions) are caused by NAHR between LCR that are located less than 5 to 10 Mb from each other and have greater than 97% DNA sequence identity. The fixed position of these LCRs and SDs in the human genome result in recurrent rearrangements having a common size for a given region. NAHR between directly oriented LCRs leads to deletions or reciprocal duplications of the genomic region located between them, and NAHR between the oppositely oriented LCRs results in an inversion of the intervening genomic segment. Interestingly, the strand exchanges for NAHR sites are not scattered throughout the entire length of homology within LCRs, but instead cluster in recombination hot spots.

Most nonrecurrent CNVs appear to occur by nonhomologous recombination mechanisms, and one often observes microhomology at the breakpoints. One prominent mechanism, particularly for complex (e.g., deletion/normal/duplication) rearrangements is the microhomology-mediated break-induced replication mechanism. The remainder of nonrecurrent different-sized rearrangements likely result from a nonhomologous end-joining recombination mechanism.

Microduplication and Microdeletion Syndromes

Some of the microduplication and microdeletion syndromes are caused by a copy-number change of the dosage-sensitive or haploinsufficient gene. Among the best characterized genomic disorders are common autosomal dominant peripheral neuropathies, CMT1A and hereditary neuropathy with liability (HNPP) to pressure palsies, that in more than 99% of cases are caused by duplication and deletion CNV, respectively, of an about 1.4-Mb genomic interval within 17p12 harboring a dosage-sensitive myelin gene *PMP22*. This genomic segment is flanked by two about 24-kb and about 98.7% identical LCRs, called the *proximal CMT1A-REP* and the *distal CMT1A-REP*, which serve as substrates for NAHR. Another example of common predominantly monogenic reciprocal microdeletion and microduplication syndromes include Potocki-Lupski syndrome due to dup(17)(p11.2p11.2), reciprocal to del(17)(p11.2p11.2) found in patients with Smith-Magenis syndrome. When two or more dosage-sensitive genes that are usually functionally unrelated are involved, these are referred to as *contiguous gene deletion* or *duplication syndromes*, for example, Potocki-Shaffer syndrome resulting from deletion del(11)(p11.2p11.2).

LCR-mediated recurrent microdeletion and microduplication syndromes usually have similar prevalence in different populations; however, for a few genomic disorders, significant differences in incidences in different world populations have been observed, likely demonstrating that variation of genomic architecture is a significant factor for disease susceptibility (e.g.,

17q21.31 microdeletion syndrome, Sotos' syndrome, 5q35). Examples of well-known and characterized microdeletion syndromes include Williams-Beuren syndrome (7q11.23), Prader-Willi and Angelman syndromes (15q11.2q12), DiGeorge velocardiofacial syndrome (22q11.2), microdeletion 17q21.31 syndrome, and Sotos' syndrome. For all these microdeletions, the reciprocal microduplications predicted by the NAHR model have been reported with phenotypes typically being milder. Recent studies revealed that some fraction of patients with autism and of patients with schizophrenia have deletion or duplication CNV involving specific loci (e.g., 1q21.1, 15q13.3, and 16p11.2); for 16p11.2, deletion CNV is more frequently associated with an autism phenotype, whereas duplication CNV can cause schizophrenia.

PATTERNS OF INHERITANCE

Mendelian Inheritance

Most characterized disease-associated mutations in humans can be assigned to a single gene (monogenic) or locus and segregate as a mendelian trait in an autosomal dominant, autosomal recessive, or X-linked fashion.

Autosomal dominant mutation is present in only one allele and thus is transmitted in meiosis to 50% of the gametes and is expected to manifest in half the offspring unless the trait is incompletely penetrant (e.g., in Marfan syndrome), represents variable expressivity (e.g., in cystic fibrosis), is age dependent (e.g., in Huntington disease), or lethal (e.g., alveolar capillary dysplasia). In pedigree analysis, autosomal dominant inheritance is revealed as a vertical transmission of the trait.

In an autosomal recessive trait, the affected individuals carry two mutant alleles at a specific locus that are either the same (usually in consanguineous families) or different. In general, both mutations are inherited from unaffected carrier parents (note that occasionally heterozygous carriers of the mutated allele may manifest a mild phenotype or have an increased susceptibility to complex or multifactorial traits). Theoretically, affected probands represent 25% of the progeny; two thirds of the unaffected siblings carry one mutated allele, and the remaining one fourth of all progeny (one third of unaffected) have two wild-type alleles. In pedigree analysis, autosomal recessive inheritance is observed as horizontal transmission of the trait.

In X-linked (both dominant and recessive) diseases, no male-to-male transmission is observed, and all daughters of affected fathers are obligate carriers of the mutated allele. X-linked dominant diseases are more rare than X-linked recessive disorders and present both in males and in females. Usually, there are twice as many affected females as males; however, if the disease is lethal in males, only females are affected (e.g., Rett's syndrome). Because of X-inactivation, the phenotype in females is milder than in males. In an X-linked recessive trait, only males are affected; in female carriers, the X chromosome harboring a mutated recessive allele is preferentially inactivated by nonrandom X-inactivation. However, females with an incomplete or skewed X inactivation, females with only one X chromosome (Turner's syndrome), or females carrying a balanced translocation between the X chromosome and an autosome (X material on the derivative chromosomes is not inactivated) can manifest the X-linked recessive disease.

Nonmendelian Inheritance

The occurrence of sporadic cases of the disease can be explained by a classic mendelian inheritance, such as de novo autosomal dominant, autosomal recessive, or X-linked mutation; however, one has to consider other possibilities, including nonmendelian inheritance—genomic imprinting, uniparental disomy, mosaicism, mitochondrial DNA mutations, and digenic or triallelic inheritance.

Some genes acquire different activity status (usually methylation) after passage through spermatogenesis compared with oogenesis. As a result, a gene can be silenced (imprinted), depending on the parent of origin. This parent-of-origin effect is observed for the *UBE3A* gene on chromosome 15q12 that is imprinted during spermatogenesis, and only the maternal copy is active. When the active maternal copy of *UBE3A* is mutated, deleted, or inactivated in a different way, the offspring is affected with Angelman's syndrome.

Sporadically, a chromosome pair may not be inherited from both parents. This distortion from biparental inheritance, termed *uniparental disomy* (UPD), may have clinical consequences when the uniparental chromosomes contain an autosomal recessive mutation or an imprinted gene. When both homologues are inherited from one parent, it is referred as *heterodisomy*. In isodisomy, both homologues in an offspring originate from only one of the parental homologues. The most common mechanism for UPD is trisomy rescue, in which an early postzygotic embryo is trisomic, as a result of chromosome nondisjunction in meiosis I, and the extra chromosome is then lost during further development to restore disomy. Because this is a random event, in one third of cases, the disomic chromosomes remaining after trisomy to disomy rescue will represent UPD. Consequently, UPD is associated with advanced maternal age.

In some diseases, pathogenic mutations have been found in single alleles of two different genes with the other alleles at each given locus being normal. This double heterozygous phenomenon of two interacting genes has been reported, for example, for *ROM1* and *RDS* in retinitis pigmentosa and *GJB6* and *GJB2* in deafness.

In some patients, three abnormal alleles in two different genes have been identified. The phenomenon of triallelic (or oligogenic) inheritance has been observed, for example, in Bardet-Biedl syndrome, familial hypercholesterolemia, and cortisone reductase deficiency. Monogenic chromosomal microduplication syndromes (e.g., CMT1A) can also be categorized as triallelic given the presence of three alleles at a given locus owing to duplication CNV.

Another distortion from mendelian inheritance can be caused by mosaicism. Two or more cell lines can be present either in the gonads only (germline mosaicism) or in somatic cells. Mosaicism should be suspected when healthy parents have two or more children with a dominant disease. Mosaicism can be particularly relevant when mutational processes involve DNA replication errors and occur mitotically (e.g., point mutation and microhomology-mediated break-induced replication).

Very rarely, a disease trait is transmitted to daughters and sons only from mothers. In such cases, one should consider a mitochondrial disease. Mitochondrial DNA (mtDNA) is present in multiple copies in the cell cytoplasm and is transmitted to progeny only through the oocytes. Initial clinical signs and symptoms typically originate from the most energy-dependent tissues (e.g., eyes, brain, skeletal muscle, and heart), and the phenotypic expression among family members varies and depends mainly on the proportion of mtDNA in the cytoplasm that carries the mutation, that is, heteroplasmy.

ASSAYING GENETIC VARIATION

Chromosome aberrations larger than about 5 Mb can be detected by light microscopy after specific staining that reveals characteristic banding patterns (e.g., G-banded karyotype analysis). Submicroscopic rearrangements, such as microdeletions or microduplications (30 kb to 5 Mb), have been analyzed for the past two decades using molecular cytogenetic techniques such as fluorescence in situ hybridization. In these routine clinical cytogenetic techniques, usually a subpopulation of peripheral blood phytohemagglutinin-stimulated T lymphocytes is analyzed. Rearrangements of similar size (i.e., 30 kb to 5 Mb in size) can be analyzed also using pulsed-field gel electrophoresis. However, both these technologies are limited to the analysis of specific genomic regions, that is, locus-specific testing.

The recent development of array-based comparative genomic hybridization (array CGH) has enabled screening of the entire human genome for imbalances, with the level of genome resolution depending only on the number, size, and distance between the arrayed interrogating probes. These genome-wide imaging techniques are analogous to digital photography wherein the resolution observed is dependent on the pixels used. Initial clinical array CGH used large genomic clones, BACs and PACs (bacterial or P1 artificial chromosomes), as interrogating probes. Recently, they have been replaced by oligonucleotides, of which millions can be synthesized on one glass slide. Oligonucleotide probes are also used on SNP arrays that, in contrast to microarray-based CGH, enable association studies or detection of uniparental disomies.

For detection of genomic imbalances, an alternative quantitative polymerase chain reaction–based technique, multiplex ligation-dependent probe amplification (MLPA) has been developed. MLPA is an inexpensive, simple, rapid, and sensitive tool to detect dosage alterations in selected genomic regions.

Most recently, several next-generation sequencing (NGS) technologies have been developed that enable massively parallel DNA sequencing reactions simultaneously and thus whole genome sequencing, or sequencing of the entire genome of an individual, to enable the determination of a Personal Genome Sequence (Fig. 40-5). In NGS, DNA sequencing uses chemistries other than the traditional Sanger dideoxy chain termination method. NGS methods generate far larger quantities of data at less expense; however, the individual raw sequence reads that are generated from individual amplified DNA template sequences have shorter read lengths and lower quality. Nevertheless, massive redundant sequencing of a personal diploid human genome

(e.g., 30-fold coverage with respect to the haploid human reference genome sequence) can provide a robust and accurate Personal Genome Sequence.

CONCLUSION

Mutations in humans are caused by SNVs and CNVs. New mutations can contribute to sporadic disease. The total genomic load can be important to a clinical phenotype. Individual genetic variation is extensive. It is a sobering thought that for more than 90% of the annotated genes in the reference human genome, a function remains to be elucidated for the potential clinical consequences of mutations. Furthermore, 98% of the human genome is noncoding, and the functional consequences of variation within it cannot be assisted using the genetic code.

THE INHERITED BASIS OF COMMON DISEASES

DAVID ALTSHULER

A central question in medicine is to understand why some people get sick and others do not. We seek these answers for multiple reasons: to provide explanations to our patients, to improve our ability to predict disease risk, and most importantly, to understand pathophysiology as a foundation for designing rational approaches to prevention and therapy. In some cases, a single environmental exposure is found to play a major role in disease (e.g., smoking and lung cancer, or human immunodeficiency virus infection [HIV] and acquired immunodeficiency syndrome [AIDS]). In others, such as Huntington's disease or cystic fibrosis, mutation of a single gene is necessary and can be sufficient to cause illness. Such singular answers are the exception; in most cases, disease is attributable neither to a single environmental factor nor to mutation of a single gene. Rather, most cases of disease result from the combined action of inborn and somatically acquired alterations in gene sequence, environmental and behavioral exposures, and bad luck. Such disorders, which make up most of the morbidity and mortality in the population, are termed *complex traits*.

Human genetics is a unique tool for generating new hypotheses about the root causes of disease, based on genome-wide searches in the human population that are unlimited by prior assumptions about underlying pathophysiologic processes. Because the sequence of the human genome and much of its common variation is now known, and given emerging tools and methods to directly determine genome sequences of individuals, we are entering an era in which medicine can be informed by knowledge of the specific genes and variants that contribute to risk for common human diseases.

HERITABILITY: INHERITED VARIATION IN DISEASE RISK

Susceptibility to disease varies within and across human populations. Studies of *familial aggregation* can determine the extent to which inheritance contributes to these patterns. These studies are simple in concept and ask whether members of the same family display more similar rates of disease than do individuals chosen at random from the population. Of course, familial clustering can reflect not only shared genes but also shared environment. The contribution of shared genotype can be dissected further by comparing rates of disease within families as a function of the extent of genetic relatedness. The cleanest such design involves the comparison of disease concordance among dizygotic and monozygotic twin pairs. For common diseases such as types 1 and 2 diabetes mellitus, obesity, hypertension, coronary artery disease, autoimmune diseases, common cancers, schizophrenia, and bipolar disease, twin studies have documented that rates of concordance are significantly higher in monozygotic than in dizygotic twin pairs. For many other traits of clinical interest (e.g., most drug responses), formal tests of heritability have not yet been performed, and the role of inheritance in these characteristics is less well documented.

Data about familial aggregation allow the calculation of *heritability,* or the fraction of interindividual variability in disease risk attributable to additive genetic influences. The remaining variability among individuals is due to all other contributions: environmental influences on disease, nonadditive (*epistatic*) genetic effects (e.g., gene-gene interactions or gene-environment interactions), error in the measurement of relatedness or disease, and random chance. For most clinically important traits (diseases and risk factors), empirical estimates of heritability range from 20 to 80% (see Online Mendelian Inheritance in Man, available at *www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=OMIM,* for comprehensive information).

When interpreting estimates of heritability, it is important to consider two crucial factors: the effect of measurement errors and the environmental context. *Measurement errors* can decrease the estimate of the heritability of a trait. A single measurement of blood pressure is much less heritable than a composite score based on serial measures of blood pressure over time. That is, day-to-day variability and imprecision in clinical measures can obscure an underlying biologic susceptibility that is entrained by inheritance. For the patient and physician, this means that although the blood pressure on a given day may not be particularly heritable, the blood pressure over time (which is presumably the relevant risk factor for vascular disease) is heritable to a much greater extent.

Second, estimates of heritability must be interpreted in the context of the environment in which the study was performed. In the case in which environmental triggers of disease are relatively constant across a study population, inherited factors may explain much of the variation in rates of disease. In contrast, in the case in which exposure to environmental causes of disease is highly varied across the study population, nongenetic factors may outweigh the contribution of inborn susceptibility. For example, the rate and diversity of smoking behavior will have a major impact on how much of the variability in rates of lung cancer (in any given study or patient cohort) may be explained by inheritance. If nobody smoked (or everyone smoked), little of the variation in lung cancer risk would be due to smoking behavior; if, in contrast, half the population smoked multiple packs a day, and the other half not at all, this behavior would no doubt dominate over inborn susceptibility.

For these reasons, heritability is not a fixed characteristic of a given disease, but an assessment of a given population, set of measurements, and the extent to which variability in genetic and environmental exposure explains disease risk. This sheds light on what is sometimes thought to be a contradiction between rates of disease being highly heritable (in a given population) and yet varying dramatically across populations separated by time, geography, or socioeconomic status. In broad comparisons across groups, environmental exposure and methods of clinical ascertainment can vary substantially and contribute to secular changes in patterns of disease. Conversely, within a group exposed to a relatively uniform environment and studied in a standardized manner, genetic susceptibility may play a major role in determining individual risk.

HETEROZYGOSITY: INHERITED VARIATION IN GENOME SEQUENCE

Heritability expresses the patterns of inherited variation in rates of disease; *heterozygosity* expresses the rate of inherited variation in genome sequences (Table 41-1). Heterozygosity is defined as the proportion of sites on the chromosome at which two randomly chosen copies differ in DNA sequence. Because cells are *diploid* (carry two copies of the genome sequence) and because these two copies were selected in a semirandom manner from the population, heterozygosity is equivalent to the fraction of base pairs that vary between the two copies each of us inherited from our mother and our father. That is, heterozygosity is the rate of genetic variation in the individual.

Single-nucleotide polymorphisms (SNPs) are sites at which a single letter in the DNA code has been swapped for a single alternate letter. Such variants are observed at approximately 1 in 1000 positions in the human genome sequence. In the protein coding regions of genes, rates of genetic variation are lower—less than 1 in every 2000 bases; the rate of variation that substantially alters the sequence of the encoded protein is lower still (see Table 41-1). These rates can be understood in light of darwinian selection against changes that alter the amino acid sequence of encoded proteins.

Genomes also contain larger scale variation: insertions and deletions of nucleotides, alteration in the number of copies of particular genes and sequences, and larger-scale alterations such as inversions and translocations. Both SNPs and larger-scale alterations can influence gene function and contribute to disease.

TABLE 41-1 CHARACTERISTICS OF HUMAN GENOME SEQUENCE VARIATION

Length of the human genome sequence (base pairs)	3,000,000,000
Number of human genes (estimated)	20,000
Fraction of base pairs that differ between the genome sequence of a human and a chimpanzee	1.3% (1 in 80)
Fraction of base pairs that vary between the genome sequence of any two humans	0.1% (1 in 1000)
Fraction of coding region base pairs that vary in a manner that substantially alters the sequence of the encoded protein	0.2% (1 in 5000)
Number of sequence variants present in each individual as heterozygous sites	3,000,000
Number of amino acid–altering variants present in each individual as heterozygous sites	12,000
Number of sequence variants in any given human population with frequency of >1%	10,000,000
Number of amino acid polymorphisms present in the human genome with a population frequency of >1%	75,000
Fraction of all human heterozygosity attributable to variants with a frequency of >1%	98%

The genetic variation in each of us is due largely to common variants. Empirically, more than 98% of the heterozygous sites in each individual display frequency of greater than 1% in the worldwide human population. Because most human heterozygosity is due to common variants, a database containing all common (>1% frequency) sequence variants in the human population can be constructed by sequencing the genomes of only hundreds of individuals, and yet would capture most of the genetic variation in any individual.

Built on the foundation of the human genome project, a catalogue of common DNA variants has been created by a series of public-private projects, including the SNP Consortium, International HapMap, and 1000 Genomes Projects. At the time of this writing, the public database contains more than 17 million human genetic variants (*www.ncbi.nlm.nih.gov:80/SNP/index.html*). Not all these entries represent common variants (some are rare), and some may represent technical false-positive findings. Nonetheless, the existing collection represents most of the common variants in each individual and has fueled efforts to systematically measure genetic variants for their contribution to disease.

The major role of common variation in human sequence diversity is explained by the unique demographic history of the human population. Despite the global distribution of the current human population, it is now clear that all people on the planet are the descendants of a single population that lived in Africa only 10,000 to 40,000 years ago. The ancestral population was small (with an effective size of perhaps 10,000 individuals), lived a hunter-gatherer existence at low population densities (relative to other humans and later domesticated animals), and had evolved in Africa over millions of years. Most human genetic variation arose in this phase of human history, before the more recent migrations, expansions, and invention of technologies (e.g., farming) that resulted in widespread population of the globe. Most common human genetic variation predates the Diaspora and is shared by all populations on earth.

A second factor is the slow rate of change in human DNA. Mutation and recombination occur at very low rates: on the order of 10^{-8} per base pair per generation. And yet, any pair of human genes traces a lineage back to a shared ancestor who lived on the order of 10^3 to 10^4 generations ago (if a generation is 20 years, then 10^4 generations is 200,000 years). In other words, considering the typical nucleotide in two unrelated humans, it is more likely that they trace back to a shared ancestor without any mutation having occurred than it is that a mutation has arisen in the intervening time. This explains why 99.9% of base pairs are identical when any two copies of the human genome are compared.

Another aspect of human variation is explained by these simple mathematical and population genetic relationships: the extent of human DNA sequence diversity attributable to rare and common variants. Each of us inherits from our parents some 3 million common polymorphisms (classically defined as those with frequency of >1%). We inherit common variants that are shared by apparently unrelated individuals but do not reach a frequency of 1% or higher. Finally, we inherit thousands of variants that are unique to each individual and their closest relatives. The question of how these different classes of variants influence disease is of central interest and importance to medical genetics.

The shared ancestry of human populations explains another aspect of human genetic variation: the correlations among nearby variants known as *linkage disequilibrium,* or *haplotypes.* Empirically, individuals who carry a particular variant at one site in the genome are observed to be more likely than chance to carry a particular set of variants at nearby positions along the chromosome. That is, not all combinations of nearby variants are observed in the population, but rather only a small subset of the possible combinations. These correlations reflect the fact discussed earlier that most variants in our genomes arose once in human history (typically long ago) and did so on an arbitrary but unique copy carried by some individual in the population. The ancestral copy of the genome on which the mutation occurred can be recognized in the current population as a stretch of particular alleles (known as a *haplotype*) that track together in the population. That is, although most variations in our genome arose before written human history, the DNA sequence in each of us carries a record of the evolution and demographic history of the human population.

These ancestral haplotypes, passed down from shared prehistoric ancestors in Africa, can be recognized in the current human population. The haplotype structure of the human genome offers a practical tool in association studies of human disease because it is not necessary to measure directly each nucleotide in order to capture much of the information. Such haplotype-based methods are the foundation for genome-wide association studies, discussed later.

THE SEARCH FOR GENES UNDERLYING MONOGENIC DISEASES

The *genetic architecture* of a disease refers to the number and magnitude of genetic risk factors that exist in each patient and in the population and their frequencies and interactions. Diseases can be due to a single gene *(monogenic)* in each family or to multiple genes *(polygenic)*. It is easiest to identify genetic risk factors when only a single gene is involved and this gene has a large impact on disease in that family. In cases in which a single gene is necessary and sufficient to cause disease, the condition is termed a *mendelian* disorder because the disease tracks perfectly with a mutation (in the family) that obeys Mendel's simple laws of inheritance.

Some single-gene disorders are caused by the same gene in all affected families; for example, cystic fibrosis is always caused by mutations in *CFTR*. Although many individuals with cystic fibrosis carry the same founder mutation (δ-508), others carry any pair of a wide variety of different mutations in *CFTR*. The existence of many different mutations at a given disease gene is known as *allelic heterogeneity.*

A mendelian disorder can be due to a single genetic lesion in any given family, but in different families can be due to mutations in a variety of genes. This phenomenon, termed *locus heterogeneity,* is illustrated by retinitis pigmentosa. Although mutation in a single gene is typically necessary and sufficient to cause retinitis pigmentosa, there are dozens of different genes in which retinitis pigmentosa mutations have been found (Online Mendelian Inheritance in Man #268000). In each family, however, only one such gene is mutated to cause disease.

Most single-gene disorders are rare (present in <1% of the population) and are manifested early in life. Many are severe and cause death before reproduction in the absence of modern medical care. The fact that most monogenic disorders are severe in childhood and rare in the population is probably not a coincidence, but reflects the impact of *natural selection.* The deleterious effect of these mutations results in a decrease in reproductive fitness (in individuals unlucky enough to inherit them), and the mutations and the disease are therefore unlikely to drift to high frequency in the population.

There are exceptions to this general idea: cases in which the mutation causing a severe monogenic disease (such as *HbS,* the cause of sickle cell anemia) is common in the population at large. Such cases appear to be the result of a different kind of selection, known as *balancing selection*—situations in which a gene mutation is beneficial in one circumstance (a genotype or environment) but deleterious in another. Heterozygous carriers for *HbS* are relatively protected against malaria, and this benefit balances the deleterious effect of sickle cell disease in homozygotes.

Starting in the 1980s, the advent of genome-wide linkage analysis led to rapid success at identifying the specific genetic mutations that

cause mendelian disorders, with hundreds of genes identified for clinically important conditions (for comprehensive information, see *www.ncbi.nlm.nih.gov:80/entrez/query.fcgi?db=OMIM*). Progress was sparked by the development of a suite of powerful research techniques—*family-based linkage analysis* followed by *positional cloning*—in which a genome-wide search is undertaken for the causal gene, which is first localized to a chromosomal region. (The initial idea of genetic linkage mapping traces to Sturtevant in fruit flies in 1913 but did not become practical in humans until the 1980s.)

Once the search has been focused by the discovery of linkage between a chromosomal region and a disease, that chromosomal neighborhood is scoured for the genetic culprit, which is recognized based on the observation of mutations that alter the protein coding sequence, and are enriched in cases of disease compared with unaffected relatives and population-based controls. The power of these approaches prompted and was fuelled by the Human Genome Project, which provided the foundation of information on DNA structure, sequence, and genetic variation required to undertake such searches.

GENETIC INVESTIGATION OF COMMON DISEASES

Similar to mendelian disorders, most common diseases are influenced by inheritance. In contrast to mendelian disorders, however, the genetic contribution to common diseases appears to be due to the action of many genes rather than a single gene in each family. Empirical evidence in favor of this model comes from efforts to use the same approach (positional cloning) for complex traits that was applied successfully to monogenic disorders.

In the 1990s, the tools of family-based linkage analysis were applied to nearly all common disorders. Much of this work was done in isolated founder populations (such as Finland and Iceland) with the goal of simplifying the genetic architecture and accessing extended pedigrees. Excepting a few notable successes, however, these studies revealed few strong signals that localized the genes responsible for disease. In most of the hundreds of such studies that have been published, there are many weak statistical signals (few if any are statistically significant given the large number of hypotheses tested) and little agreement between different studies of the same disease.

In view of the well-understood statistical power of family-based linkage methods (based on their extensive use for monogenic disorders) and their relatively limited success despite extensive efforts in common diseases, it was concluded by most investigators that rare variants in single genes do not explain a large fraction of the risk for common diseases. If a single gene contained rare mutations of large effect that explained 20% or more of the inherited risk for type 2 diabetes, hypertension, or schizophrenia, it is likely that its location would long since have been found based on linkage analysis.

A next potential shortcut to understanding the genetic determinants of common diseases is to identify and study rare, early-onset forms of diseases that clearly demonstrate mendelian patterns of inheritance. Because these families display patterns of inheritance consistent with a major gene of large effect, the powerful tools of positional cloning can be and have been used successfully to identify the genes responsible. Important examples include the role of *BRCA1* and *BRCA2* in early-onset breast cancer, maturity-onset diabetes of the young as a form of type 2 diabetes, many monogenic disorders of blood pressure and electrolyte regulation, early-onset Alzheimer's disease, and many others.

These successes provide diagnostic information for families burdened with severe, early-onset forms of disease and insight into the underlying pathways responsible for disease. For example, more than 20 genes have been identified that, when mutated, cause rare mendelian disorders of blood pressure and electrolyte regulation. So far, every one of these genes is active in the kidney, and most are involved in the renin-angiotensin-aldosterone pathway. This result is a compelling demonstration of the central importance of the kidney in human blood pressure regulation and has suggested new therapeutic targets of substantial promise.

It was hoped that the genes found to be responsible for early-onset, monogenic forms of common diseases would contribute to the more common forms of disease in the population. In this scenario, severe mutations might cause early-onset forms, and more prevalent but subtle alterations in the same genes might contribute to common forms of disease. A comprehensive test of this hypothesis awaited tools from the human genome project and improved methods of genetic epidemiologic analysis.

ASSOCIATION STUDIES: FROM CANDIDATE GENES TO GENOME-WIDE ASSOCIATION STUDIES

Genome-wide association studies (GWAS) are simple in concept. A genetic variant is identified, its frequency is measured in individuals with the disease of interest, and it is compared with well-matched controls (drawn from the population at large or unaffected family members). This process can be repeated for as many genetic variants as exist—up to and including a genome-wide collection. Appropriate analyses need be performed to rule out alternative explanations for an association to disease, such as mismatching of cases and controls, or technical artifacts. Because the null distribution is well described (under the hypothesis of no association between genotype and phenotype), it is possible to calibrate such analyses and to identify reproducible associations from out of the large sea of benign polymorphisms.

Genetic association studies were pioneered in the context of the *HLA* locus on chromosome 6. The *HLA* was discovered based on its role in transplantation tolerance and is characterized by diverse allelic variation that can be measured based on interactions of antibodies and antigens. By measuring these protein-based (immunologic) readouts of the underlying genetic variation, *HLA* alleles were found to be a major determinant of susceptibility to infectious and autoimmune diseases. Starting in the 1960s, empirical data on human population genetics and genetic association studies were developed in the context of the *HLA*.

By the 1980s, tools of molecular biology made it possible to directly measure DNA variation (rather than using protein or phenotype measurements as surrogates for the underlying genetic variation), ushering in the modern era of human genetic research. In this pregenomic era, it was only practical to measure one or a small number of genetic variations in each study, limiting association studies to incomplete assessments of individual "candidate" genes selected based on biologic criteria.

The study of candidate genes led to a modest number of robust and reproducible associations, such as the contribution of Apo-ε4 to Alzheimer's disease; factor V Leiden to deep venous thrombosis; a 32-base deletion in the chemokine receptor CCR5 to HIV infection; common variants in the insulin gene to type 1 diabetes; SNPs in the peroxisome proliferator-activated receptor γ (PPAR-γ) and the β-cell potassium channel Kir6.2 to the risk for type 2 diabetes.

By early in the 2000s, comprehensive surveys of published genetic association studies showed that valid associations were few and far between, with many initial claims of association proving irreproducible, likely representing false-positive claims. One such analysis estimated that, in the pre-GWAS era, only 10 to 20 bona fide associations had been documented of common genetic variants with common diseases.

A major reason for the state of this literature was the intrinsically low likelihood of finding a gene and variant contributing to any given disease. Each genome contains millions of genetic variants, and presumably only a small fraction of these influence disease. This is often described as a problem of "multiple hypothesis testing," with the investigative community searching for associations between multiple genes, multiple variants in each gene, and multiple diseases. An alternative (bayesian) statistical framework frames this issue based on low prior probabilities of association. Regardless, it is conceptually clear that much more stringent statistical thresholds (than the traditional $P < .05$) are required for declaring association of genetic variants and disease.

As in linkage analysis for mendelian traits, a key to success in association studies was the advent of genome-wide search, unbiased by prior hypotheses about biologic mechanisms. With the sequencing of the human genome, development of large-scale SNP databases, and tools for genotyping up to 1M SNPs per individual, by 2005 it became practical to perform GWAS to identify genomic loci harboring allelic variation. With a recognition that any given variant had a very low likelihood of truly being associated with disease, much more stringent statistical thresholds were deployed (typically requiring a P value of 10^{-7} or lower to declare "genome-wide significance").

Age-related macular degeneration (AMD) provided an early success of GWAS. AMD is a typical common, polygenic disease (Chapter 431); siblings of affected patients are perhaps three to six times as likely as unrelated individuals to become afflicted, and yet family-based linkage analysis revealed only modestly significant (and modestly reproducible) linkage results. The pathophysiologic defects that underlie AMD were largely unknown until it was found that a common coding polymorphism in the gene for complement factor H is a major risk factor for AMD. The variant *(Y402H)* has a high population frequency (approximately 35% in European populations) and

increases risk by 2.5- to 3-fold in heterozygotes and by 5- to 7-fold in homozygotes. Multiple other complement factors have since been found to harbor common genetic variation that influences the risk for AMD in a highly reproducible manner, providing unambiguous information about the primary role of complement in this common disease.

Since 2005, GWAS has been used to identify literally hundreds of novel genetic variants that show reproducible associations to a large variety of common human diseases. The field evolved a set of criteria and standards that largely eliminated the previous difficulties with irreproducible claims of association, making association studies a reliable method to identify genomic loci related to human diseases. The National Human Genome Research Institute of the National Institutes of Health maintains a catalogue of GWAS findings (www.genome.gov/26525384) that, at the time of this writing, included 904 such associations for 165 traits. This represents rapid progress compared with the two dozen or so such findings known at the start of the decade.

The results of GWAS support a number of conclusions about the role of common genetic variants in common disease. First, most diseases investigated by GWAS have yielded novel findings, suggesting that the approach has general utility. Second, only a small fraction of these findings were previously known, indicating that new clues can be obtained by genetic mapping of common diseases. Third, most of the associations demonstrate extremely modest odds ratios (on the order of 1.1-fold to 1.5-fold), indicating that natural selection has purged alleles of large effect from the pool of common variants. Fourth, most of the associated SNPs lie in noncoding regions, suggesting that they act through effects on gene regulation rather than directly altering protein-coding sequences. Fifth, only a modest fraction of the estimated heritability of each disease has yet been explained, indicating a role for other common variants of more modest effect, rare variants, genetic interactions, or other (as yet unanticipated) influences.

Because GWAS are genome-wide (not limited to "candidate" genes), they provide a test of the hypothesis that prior investigations had identified sets of genes relevant to each disease (relevant, that is, through the lens of genetic variation and inheritance). In the case of autoimmune diseases, many (perhaps half) of the 100 or more findings from GWAS lie near a gene previously known to play a role in the immune system. Similarly, a substantial fraction of the genetic variants found to influence lipid levels lie near genes that were previously known to play a role in lipid biology (because they were known already either through rare mutations that contribute to mendelian forms of hyperlipidemia or through biologic investigations). These findings confirm that the basic pathophysiologic mechanisms already known can be "validated" through the lens of inherited risk factors and encourage investigation of the new findings offered by GWAS.

In contrast, for some diseases, most of the genetic variants found are novel and do not lie near genes previously studied. One such case is type 2 diabetes, for which 35 independent genomic loci have been found to influence risk for disease, and yet only a handful were previously implicated by other methods. This may indicate and illuminate gaps in our previous knowledge of the pathophysiology of type 2 diabetes.

Although tantalizing, the results of GWAS have raised many more questions than they have answered. These discoveries implicate particular genomic regions, but to date in only a few cases have the causal genes been proved. This is challenging in large part because so many of these common variants are noncoding, and it remains difficult to connect noncoding variation to the genes thereby regulated. To the extent that truly novel genes are identified, much work is needed to discover their biologic and physiologic functions. Finally, GWAS findings explain only a modest fraction of the estimated heritability of most diseases, leaving open the question of which genes, and which types of variants and genetic effects, explain the remainder.

FROM COMMON VARIANTS TO INDIVIDUAL GENOMES

Although much of human genetic variation is due to common DNA variants (such as those tested through GWAS), each of us also inherits many thousands of variants that arose more recently and that tend to be lower in frequency and more population specific. To the extent that such variants have very large effects on phenotype, they may have been previously identified based on family-based linkage studies of mendelian disorders. However, there almost certainly exists a large universe of lower-frequency variations that are too rare to have been captured by the first generation of GWAS and that have effects too modest to have been recognized and identified in family-based linkage analyses.

The study of such lower-frequency and rare variants is now becoming practical owing to advances in technology for DNA sequencing. With dramatic drops in price and increases in throughput, it is increasingly practical to sequence individual genomes in the context of medical research (and, in the future, clinical practice). Such an approach will provide a much more complete assessment of genetic variation than was previously obtainable and will incorporate common as well as rare variants.

The first task will be to develop methods to interpret the millions of variants in each genome. Variants of high frequency have already been well studied by GWAS, and each is increasingly annotated with information about disease association. For variants that are lower in frequency, but still observed in a substantial number of unrelated individuals, the basic association methodology can be applied. That is, the frequencies of each specific variant can be measured in affected cases and in unaffected controls and compared with an appropriately constructed null distribution and statistical threshold. Moreover, the availability of a much more complete database of DNA variation (as is being created by the 1000 Genomes Project) will lead to a second generation of GWAS that is more complete for lower-frequency variation.

Many DNA variants will be unique to individuals (and their close relatives), however, and will require different approaches. If the analysis includes a large pedigree, with multiple affected and unaffected relatives, it may be possible to perform the association analysis in single families. More typically, however, it will be necessary to analyze large sets of samples, measure the rate of different (individually rare) variants in each gene, and compare these rates between cases and controls.

In the distant future, we may learn to "read" genome sequences and predict the effect of a variant never before observed. For the foreseeable future, however, interpretation will require statistical analysis of genomes, documenting that variation in particular genes is robustly and reproducibly associated with each particular disease.

IMPLICATIONS AND FUTURE DIRECTIONS

Inherited factors contribute substantially to common as well as rare diseases. Mendelian disorders are typically caused by rare mutations in the protein-coding regions of genes. Common variants, investigated through GWAS, have typically modest effects and often act through noncoding effects on gene regulation. Each of us carries a deep reservoir of less common variation that will soon be tested for a role in disease using methods of next-generation DNA sequencing. It seems reasonable to expect that an integrative analysis of this information will result in a defined list of genes and variants in those genes (both common and rare) that contribute to each human disease.

Success identifying genes and mutations will only prove of value if it leads to improved prediction, diagnosis, understanding, and treatment. Prediction and personalized medicine require a foundation of evidence that demonstrates clinical benefit. This will involve incorporating DNA variation in epidemiologically valid cohorts and testing particular approaches to genetic prediction in clinical trials. The fact that some genetic tests may prove predictive in no way means that routine genome sequencing will be useful to patients, and much work will be needed to offer the public and physicians guidance in interpreting such data.

Biologic understanding requires bedside-to-bench research, in which genes found as mutated in patients are studied in the laboratory. It will be necessary to place these new genes into known (and as yet unrecognized) biologic pathways and to understand how dysfunction and dysregulation lead to disease. In some cases, such as the role of complement in AMD (see earlier), initial answers may come quickly; in others, in which the relevant pathobiology is as yet unknown, the information to be gleaned from following these clues is unpredictable. Presumably, in the fullness of time, the genetic insights gleaned from patients will lead to a new generation of therapies that more directly target the underlying root causes of risk in the population. What is most certain is that genetic and genomic information is accumulating at a staggering rate and holds both much potential and much challenge for the future of medicine.

APPLICATION OF MOLECULAR TECHNOLOGIES TO CLINICAL MEDICINE

GEOFFREY S. GINSBURG

MOLECULAR TECHNOLOGIES ALONG THE CONTINUUM FROM HEALTH TO DISEASE

Along the continuum from health to disease (as shown in Fig. 42-1), there are now several important points in clinical decision making for which molecular technologies are being applied to health care (Table 42-1). Using DNA-based approaches, risk estimates for developing some diseases can now be quantified during health and possibly even at birth. Molecular signatures from technology platforms that measure the expressed genome (RNA, proteins, metabolites) now allow interventions at the level of the individual by defining physiologic states in response to our environment that predict future clinical outcomes. These methods can also provide more precise ways to screen for and to detect disease at its earliest molecular manifestations. Similarly, they are the basis for a new molecular classification of disease and diagnosis that foretells prognosis. The selection of certain drugs now may be guided by a patient's underlying genetic makeup as well as the molecular makeup of the disease. Given that a disease's evolution from baseline risk often occurs over many years, molecular profiling over time defines a novel form of health care that focuses on disease prevention and proactive management rather that the current paradigm of acute intervention and crisis management.

GENES, GENOMES, DISEASE, AND TREATMENT

A key question in medicine is to what extent genetic variation influences the likelihood of disease onset, affects the natural history of disease in combination with the environment, or provides clues relevant to the management of disease. And it is not just the human genome that is relevant to an individual's state of health—the genomes of thousands of microorganisms are relevant to human phenotypes, and insights from their genomes are providing new approaches for the diagnosis, study, and treatment of disease (see Microbiome).

Variation in the Human Genome

It is now estimated that any two randomly selected individuals have sequences that are 99.5% identical, or that an individual genome would be heterozygous at approximately 15 to 25 million positions. Most of the differences involve a single base in the DNA code, referred to as single nucleotide polymorphisms (SNPs). The remaining variation consists of insertions or deletions of short sequence stretches, and copy-number variation (CNV) in the number of repeated elements at a particular locus in the genome. These types of variation can influence disease, and this must be accounted for in any attempt to understand the contribution of genetics to human health.

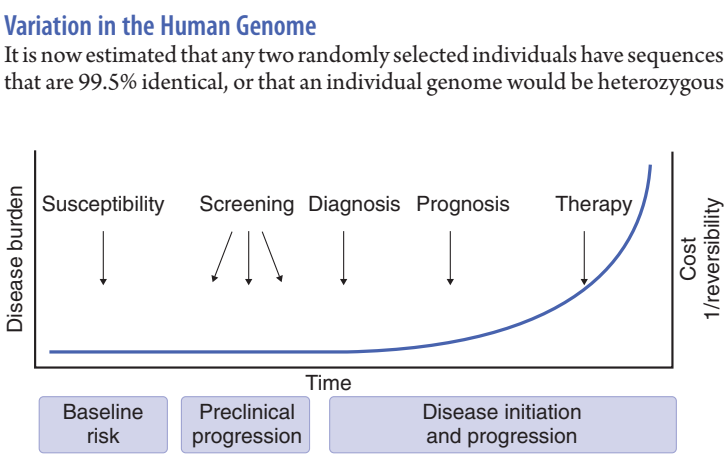

FIGURE 42-1. Use of molecular technologies across the continuum from health to disease. Various molecular technologies may be used to complement the traditional approach to evaluating at the time points indicated. SNP = single nucleotide polymorphism. (Adapted from Snyderman R. The role of genomics in enabling prospective health care. In: Willard H, Ginsburg G, eds. *Genomic and Personalized Medicine*. Burlington, Mass: Elsevier; 2009:378-385.)

Genome-wide Association Studies

The "common allele, common disease" hypothesis has been explored with notable success in a number of conditions, using large cohorts of well-phenotyped patients and high-throughput methods to genotype up to 1 million variants in the genome. Genome-wide association studies (GWAS) report the statistical association of one or more variants in a narrow genomic region with the presence or absence of the clinical condition. The reported SNPs define risk factors for that condition, at least in the populations under study, and can provide novel insights into the biology of the disease. As of December 2010, more than 3500 SNPs have been reported to be associated with more than 50 phenotypes in published studies (www.genome.gov/gwastudies/). It should be stressed that in most instances, *causality* of the reported SNP and the increased risk has not been proved; it may be that the actual causal variant is not the SNP itself but is a currently undetected variant that lies in linkage disequilibrium with the SNP. In most instances, the functional impact of the associated SNP is obscure, and it will require integrated genomic and functional studies to elucidate the precise basis for the roles of genome variation in disease.

Medical Resequencing

Resequencing specific genes in a cohort of affected individuals with disease is an alternative or complementary approach to GWAS to uncover rare variants responsible for the disease in question. It may indeed be that these more rare variants are responsible for most genetic risk, but there are insufficient data to draw conclusions. Most efforts have focused on one or several genes that are believed to be strong candidates for the phenotype under study. Using this approach, rare variants in relevant candidate genes have been detected at a statistically significant higher frequency in the genomes of patients with common clinical conditions. These early successes suggest a strategy of resequencing relevant genes in individuals at the extremes of the population distribution for measurable traits.

Somatic Mutations

It has been of interest to use medical resequencing to search for somatic mutations in tumor tissue in order to identify genes potentially relevant to cancer progression. The Cancer Genome Atlas (http://cancergenome.nih.gov/index.asp), started in 2006, has begun to explore systematically the entire spectrum of genomic changes in human cancers and has already published its first results for glioblastoma. The genes implicated in these studies tend to be different from those identified as inherited risk factors in previous genetic studies and provide novel insights into the biology of human cancer and suggest candidates for exploring mechanisms of tumorigenesis or metastasis or for developing therapeutic approaches.

Copy-Number Variation

There has been an unanticipated prevalence of structural variants in the genome that collectively account for more variation in genome sequence than do SNPs. The most common types of structural variations are CNVs. A dedicated effort is under way to catalogue CNVs in the human genome and to associate these with clinical phenotypes. Although most CNVs are inherited, some occur de novo or even in somatic cells; in these cases, an individual will have different repeat lengths from either of his or her parents. CNVs can contribute to human diseases in at least two ways:

1. *Pathogenic* CNVs are certain genomic imbalances that appear to cause neurodevelopmental diseases directly. Pathogenic CNVs are usually de novo in nature and have associated specific genomic imbalances with as many as 50 genetic syndromes (*www.sanger.ac.uk/PostGenomics/decipher/*).
2. *Benign* CNVs have been identified in healthy individuals and may have more subtle consequences on human health.

Epigenetics and the Epigenome

Epigenetic changes, in DNA methylation or in histone modification over time, in the genome may result in aberrant gene expression and human

TABLE 42-1 APPLICATION OF MOLECULAR DIAGNOSTICS ALONG THE CONTINUUM FROM HEALTH TO DISEASE: EXAMPLES

TIME POINT IN CLINICAL DECISION MAKING	*Cancer*		*Cardiovascular Disease*	
	Test	***Indication***	***Test***	***Indication***

disease in response to environmental influences. It has become clear during the past two decades that epigenetic changes (methylation) play a crucial role in carcinogenesis. Similar research is emerging on DNA methylation in other diseases, especially autoimmune and cardiovascular disorders. For example, aberrantly hypomethylated DNA in circulation in systemic lupus erythematosus (SLE) (Chapter 274) might induce an immune response because of its similarity to unmethylated microbial DNAs. Further contributions of defective methylation to SLE pathogenesis could be due to the transcription of endogenous retroviruses or the increase in the expression of certain genes related to autoreactivity. In cardiovascular disease, global DNA hypomethylation and coexisting hyperhomocystinemia have been observed. Taken together, these data reinforce the notion that methylation profiles can be highly valuable to study the pathogenesis of a variety of conditions. The National Institutes of Health have initiated the Human Epigenome Project, whose goal is to indentify, catalogue, and interpret widespread DNA methylation patterns of all human genes in all major tissues; this effort has now been expanded internationally.

Microbiome

The genome sequences of thousands of microorganisms have been determined and are being used to provide rapid diagnostic tests in clinical settings; to predict antibiotic or antifungal efficacy; to identify the source of airborne, water, or soil contaminants; to monitor hospital or community environments; and to understand better the contribution of microbial ecosystems and various environmental exposures to diverse human phenotypes. For example, the human colon contains more than 400 bacterial species comprising some 10^{13} to 10^{14} microorganisms. The gastrointestinal tract (as well as other body cavities and the skin) provides a unique environment for microorganisms, the microbiome, whose impact on human health and disease is just being explored. The genomes of the microbiota are significantly different from the human genome and have the capacity to alter the metabolic profile of different individuals or different populations, with clinically meaningful effects on drug metabolism, toxicity, and efficacy. The applications to microbiomes of approaches in genomics are revolutionizing clinical diagnostics, for example, to identify unknown viral infections or to diagnose antibiotic resistance in infections such as methicillin-resistant *Staphylococcus aureus* (MRSA). A number of diseases have been associated with large-scale imbalances in the gut microbiome, including inflammatory bowel disease, antibiotic-resistant diarrhea, and obesity.

Personal Genomics

The delivery of information from individual genomes is a fast-moving area of technology development that is spawning a social and information revolution among consumers. Dramatic improvements in sequencing technology have reduced the cost and time of resequencing projects to approach the long awaited personal "$1000 genome." What remains unsettled for now is what degree of genome surveillance will be most useful, either for research or for clinical practice. The push for incorporation of genome information into clinical practice may come as much or more from consumers as from professionals. Several companies offer genome-wide SNP profiles to the public, some with associated risk estimates for relevant clinical conditions. There is a clear and important research agenda that needs to be developed in concert with these technologic breakthroughs that allows health providers and the public to understand the information and, more importantly, to believe that it is accurate, informative, and actionable. With the vast amount of information contained in the human genome sequence, it will be critically important that the proper reading, interpretation, and communication of the information are carried out. This may be a "disruptive technology" in health care delivery, providing health and disease risk information to consumers without physician intervention and guidance. Patients are already bringing reports from these analyses to their health providers and requesting guidance. What are providers, armed with a paucity of genomic training, telling them?

Pharmacogenetics

DNA variation that is associated with response to drugs is referred to as *pharmacogenetics,* and there are now numerous examples of molecularly guided therapies that use DNA assays (E-Table 42-1). To assist clinicians in the practice of pharmacogenetics across a broad number of medications, the first microarray-based gene chip, approved both in the United States and European Union, was released in 2003 as the AmpliChip CYP450. The product was designed to identify key genetic polymorphisms in two CYP450 enzymes, *CYP2D6* and *CYP2C19*, cumulatively responsible for much of the first-pass metabolism of many currently prescribed drugs. The regulatory agencies cleared this test based solely on analytic performance and validity information, but indicated that its utility specifically for clinical application needed to be proved. Thus, clinicians remain unclear about the impact of these tests on clinical decision-making guidelines.

Perhaps the best example of a pharmacogenetic association for which the clinical relevance is clear features management of treatment with warfarin. The oral anticoagulant warfarin (Chapter 37) is prescribed for the long-term treatment and prevention of thromboembolic events, with more than 31 million prescriptions annually in the United States alone. However, because of the drug's narrow therapeutic index, a variety of complications are associated with its treatment, even after dose adjustment according to age, gender, weight, disease state, diet, and concomitant medications. Investigation of pharmacokinetic and pharmacodynamic drug properties indicated the

additive involvement of two genes in determination of warfarin maintenance dose. One of these genes encodes CYP2C9, which is responsible for most of the metabolic clearance (~80%) of the more pharmacologically potent *S*-enantiomer of warfarin. Both *CYP2C9*2* and *3 cause a reduction in *S*-warfarin clearance, with ten-fold variation seen from the genotype linked with the highest (*CYP2C9*1/*1*) to lowest (*CYP2C9*3/*3*) activity. It is estimated that *CYP2C9* variants account for 10 to 20% of the total variation in warfarin dose, with additional genetic and environmental factors playing larger roles in dose determination. The second gene is the vitamin K epoxide reductase complex protein 1 (*VKORC1*), targeted by warfarin. Consideration of *VKORC1* genotype, together with *CYP2C9* genotype and factors such as age and body size, is estimated to account for 35 to 60% of the variability in warfarin dosing requirements. Although further studies are under way, the clinical pharmacology advisory panel to the U.S. Food and Drug Administration (FDA) acknowledged the importance and potential for genotyping of *CYP2C9* and *VKORC1* during the early phase of warfarin therapy, and the drug label was amended accordingly in August 2007; however, the Center for Medicare and Medicaid Services announced in 2009 that it would not reimburse for testing until there was more evidence of a clinical benefit.

THE EXPRESSED GENOME

Gene Expression

Information from (RNA, protein, or metabolite) expression informs three areas relevant to clinical decision making:

- Disease diagnosis and classification
- Disease prognosis
- Pharmacogenomics

Disease Diagnosis and Classification

Whole-genome RNA expression data can be used to identify subtypes of cancer not previously recognized by traditional methods of analysis (Table 42-2). Among many examples, patterns of RNA expression have identified subclasses of tumors that define the acute leukemias or Burkitt's lymphoma from diffuse large B-cell lymphomas (DLBCL). Breast cancer profiling has defined four different gene expression subtypes; these molecularly defined subtypes have important prognostic relevance. Outside of cancer, complementary DNA microarray technology has proved useful for classifying a broad range of diseases, such as rheumatoid arthritis, Crohn's disease, schizophrenia, and multiple sclerosis, and for differentiating between ischemic and nonischemic cardiomyopathy.

Disease Prognosis

The first prognostic application of gene expression signatures described two molecularly distinct forms of DLBCL previously not appreciated using traditional histopathology techniques: germinal center B-like DLBCL and activated B-like DLBCL. Their clinical significance is that patients with germinal center B-like DLBCL have significantly better overall survival when treated with standard chemotherapy. Similarly, microarray studies of breast cancer have proved more powerful than traditional methods for predicting a patient's outcome, such as tumor size, lymph node status, and estrogen receptor status; for example, a 70-gene expression signature was found to be a strong predictor of metastasis, outperforming all currently used clinical predictors.

In 2009, oncologists used RNA expression signatures (Oncotype DX) for risk stratification and prognosis in more than 40,000 breast cancer patients and had cumulatively ordered more than 135,000. A prospective cooperative group clinical trial in Europe (MINDACT) aims to measure the effectiveness of a gene expression predictor of breast cancer prognosis in guiding adjuvant chemotherapy when compared with predictions based solely on the traditional clinical parameters for prognoses. A current study sponsored by the National Cancer Institute aims to use the Oncotype DX test from Genomic Health, Inc., to identify low-risk breast cancer patients unlikely to benefit from chemotherapy. For lung cancer, a similar opportunity now exists to refine prognosis and redirect treatment in early-stage disease and a clinical trial has been developed that uses this signature to randomize patients to surgical treatment with or without adjuvant chemotherapy.

Pharmacogenomics

The use of complex molecular information from the genome (as opposed to DNA variation) is often referred to as *pharmacogenomics.* (As described earlier, *pharmacogenetics* refers to individual responses to drugs as a function of DNA variation.) The expressed genome has provided several important

TABLE 42-2 PERIPHERAL BLOOD GENE EXPRESSION SIGNATURES TO CLASSIFY DISEASE STATES

	TARGET CELL	RESULTS	CHAPTER
Autoimmune	Whole blood RNA	A 41-gene signature differentiates **infliximab** responders from nonresponders.	35
	Whole blood RNA	A 29-gene signature best differentiates active from inactive **systemic lupus erythematosus.**	274
Inflammatory	Peripheral monocytes	A 53-gene signature distinguishes between patients with active **multiple sclerosis** and healthy controls.	419
	Peripheral monocytes	A 136-gene signature distinguishes active **multiple sclerosis** patients on TNF-α therapy from treatment-naïve patients.	419
	Whole blood RNA	A 10-gene-based composite score for diagnosing **atopy** and **asthma** performs better than the total IgE count, with a sensitivity and specificity of 96% and 92%, respectively.	257
Neoplasm	$CD27^+$ and $CD19^+$ B cells; $CD4^+$ T cells	A 2984-gene signature can distinguish subtypes of **diffuse large B-cell lymphoma**.	191
	Bone marrow mononuclear cell RNA	A 50-gene signature is highly correlated with **AML-ALL distinction** and is used to develop a classification scheme.	189
	$CD34^+$ blast cells RNA	A 2856-gene signature allows **classification of AML** into 16 distinct groups.	189
Transplant	$CD4^+$ and $CD8^+$ T-cell RNA	A 17-gene signature identifies donor samples **likely to cause GVHD** with 80% accuracy.	181
	Whole blood RNA	A 91-gene signature distinguishes between **transplant rejection** (grade 3A) and controls (grade 0).	48
Environmental Exposure	Whole blood RNA	A 216-gene profile differentiates **oxidative damage** from active oxidative damage in active and passive smokers.	31
	Whole blood RNA	A 62-gene profile correlates with severity of **arsenic poisoning.**	21
	Whole blood RNA	A 25-gene signature identifies **exposure to ionizing radiation** with overall accuracy of 90%.	19
Cardiovascular Disease	Platelet RNA	A 54-gene signature classifies **STEMI and stable CAD**. Moreover, MRP8/14 predicts risk for a future cardiovascular event.	71, 73
	Whole blood RNA	A 160-gene signature correlates with extent of **coronary stenosis** and is associated with atherosclerotic vascular disease.	70
	Whole blood RNA	A 14-gene signature confirmed by PCR is associated with the **presence and extent of CAD.**	71

examples of novel biomarkers that can be used to guide therapy selection. An iconic form of pharmacogenomics is "targeted therapy," of which there are now several examples in clinical practice (E-Table 42-1 and Table 42-3). Trastuzumab therapy (a monoclonal antibody specifically targeting *HER2/neu*-overexpressing breast tumors) is an example of a protein therapeutic for which an obligatory biomarker assay and diagnostic test have been developed to identify the patients most likely to benefit from this drug. Trastuzumab is marketed solely for the subset of patients (~10%) who overexpress *HER2/neu* (Chapter 204). Given the low prevalence of marker-positive breast cancers, it has been suggested that if it were not for the use of the diagnostic marker the drug would not have been successfully developed. In cardiovascular medicine, a targeted approach to acute coronary syndromes has been practiced for more than a decade with the use of cardiac troponin I (cTnI) measurements to dictate the beneficial use of glycoprotein IIb/IIIa inhibitors.

Recently, a series of gene expression signatures have been developed to predict the activation state of various oncogenic signaling pathways, thereby portending the advent of personalized cancer treatment based on a tumor's gene expression pattern. When evaluated in several large collections of human cancers, these gene expression signatures identify patterns of pathway deregulation in tumors and clinically relevant associations with disease outcomes, including prognosis. Linking pathway deregulation with sensitivity to therapeutics that target components of the pathway provides an opportunity to make use of these "oncogenic signatures" to guide the use of target therapeutics.

Proteomics

Proteomics is the large-scale study of proteins. The *proteome* often refers to the full complement of proteins and their various derivatives (e.g., splice variants or post-translational modification). In the context of health and disease, proteomics seeks to define the full set of proteins associated with a particular physiologic state. The capabilities and direction of proteomics is evolving in terms of both protein identification and differential expression between two physiologic states (such as health and a specific disease). Quantitative proteomics, in which global differences in protein abundances are measured, continues to be a priority area for biomarker discovery and molecular medicine. This area has been dominated by stable isotope approaches, but recent label-free quantitative methods have been developed that rely on the measured intensity of a peptide ion and compares this to its intensity in other samples. Label-free methods have the advantage of higher throughput and fewer sample manipulation steps. Multiple-reaction monitoring of specific peptides within biofluids allows quantitation of absolute abundance of proteins in clinical samples. Although this technology is relatively immature in its applications to human health and disease compared with RNA and metabolic profiling, it is anticipated that these methods, combined with the development of mass spectroscopy (MS) technology, will advance proteomics to more routine use in disease classification and diagnosis, prognosis, and pharmacogenomics within the next several years.

Metabolic Profiling

A metabolic profile is very similar to some of the traditional targeted profiles, such as a lipid profile, although it is more comprehensive. Metabolomics measures changes in the metabolic or chemical milieu that are downstream of genomic and proteomic alterations. It is estimated that humans contain approximately 5000 discrete small molecule metabolites, and the identification of metabolic fingerprints for specific diseases may have particular practical utility for the development of therapies because metabolic changes immediately suggest enzymatic drug targets. Similar to genomics and proteomics, metabolomics may be useful in disease diagnosis, prognosis, and drug development. In particular, metabolomics will likely be a valuable tool in assessing drug toxicity. Targeted MS-based metabolic profiling has also been increasingly applied to studies of human diseases and conditions. These tools are being applied to diverse areas, such as diabetes, obesity, cardiovascular disease, cancer, and mental disorders.

ASSEMBLING MOLECULAR INFORMATION FOR CLINICAL DECISION MAKING

Despite the potential for molecular information to transform health care, past experience indicates that new molecular interventions, like any new medical intervention, will remain substantially underused for many years unless a robust infrastructure is established for supporting their appropriate use. Moreover, molecular interventions may face even greater barriers to clinical adoption compared with more traditional medical interventions, owing to such factors as limited clinician familiarity with molecular technologies, the volume and complexity of the underlying data that may need to be considered, and financial coverage of additional testing in an already financially challenged health care system.

Of the many strategies that have been evaluated for promoting evidence-based care, one strategy has been found to be particularly effective: clinical decision support (CDS), which entails providing clinicians, patients, and other health care stakeholders with pertinent knowledge or person-specific information, intelligently filtered or presented at appropriate times, to enhance health and health care. Clinician-directed CDS interventions evaluated in randomized controlled trials have significantly improved patient care, provided that the CDS was delivered automatically as a part of clinician workflow, offered at the time and location of decision making, recommended a specific course of action, and used a computer to generate the recommendations.

Extended to molecular medicine, CDS supports its consistent and evidence-based application in health care. For example, when initiating warfarin therapy using an electronic prescribing system, a clinician could be provided with recommendations on dosing and monitoring that account for the patient's *CYP2C9* and *VKORC1* genotypes. As another example, to

TABLE 42-4 CLINICAL DECISION SUPPORT REQUIREMENTS TO APPLY MOLECULAR TECHNOLOGIES TO CLINICAL MEDICINE

NEED	AVAILABLE RESOURCES
Centrally managed repositories of medical knowledge	Authoritative knowledge on how molecular interventions should be used in clinical practice (e.g., U.S. Preventive Services Task Force, U.S. Evaluation of Genomic Applications in Practice and Prevention initiative) Repositories of structured experimental genomic and molecular data (e.g., PharmGKB for pharmacogenetic and pharmacogenomic experimental data and curated knowledge; NCBI dbGaP for data from studies evaluating the interaction between genotypes and phenotypes; and NCBI GEO for gene expression data) Large-scale efforts at managing medical information in health systems (Intermountain Healthcare, Partners HealthCare)
Standardized representation of molecular and patient data	Standardized information terminologies for both molecular and traditional patient data (e.g., HL7 data standards, including HL7 Clinical Genomics data standards and emerging HL7 virtual medical record standard; openEHR Archetypes; SNOMED CT; LOINC; BSML; MAGE-ML; National Cancer Institute/caBIG Common Data Elements)
Standard approaches for locating and retrieving patient and molecular data	Approaches for locating and retrieving patient data across systems (e.g., HL7 Retrieve, Locate, and Update Service draft standard and corresponding OMG technical specification) Regional and national initiatives for secure health data exchange (e.g., U.K. National Health Service Connecting for Health, U.S. Nationwide Health Information Network prototypes, caBIG, Indiana Health Information Exchange)
Sharing and coordination of information	Initiatives to share medical knowledge (e.g., Morningside Initiative, U.S. Federal CDS Collaboratory) Efforts to specify functional requirements of EHR systems (e.g., HL7 EHR System Functional Model standard) Coordinated use of available health information technology standards (e.g., U.S. Health Information Technology Standards Panel, Integrating the Healthcare Enterprise)

support a clinician in his or her treatment of a patient with breast cancer, an electronic health record (EHR) system could consider the gene expression profile of the patient's cancer biopsy and provide an individually tailored prediction of how the patient is likely to respond to various therapeutic options. Critical to the vision of molecular medicine supported by information technologies will be a national CDS infrastructure (Table 42-4) that enables authoritative, centrally curated knowledge of molecular information that can be consistently leveraged in clinical practices across the nation. The true application of molecular technologies will require robust CDS systems that (1) access molecular and other patient data located within the EHR, (2) evaluate and integrate this information in relation to rule sets, and (3) deliver the information in a fashion that allows real-time actionable recommendations for the individual patient.

CELL AND GENE THERAPY

KARL SKORECKI AND EITHAN GALUN

CELL THERAPY

Cell therapy refers to the provision of living cells to patients for the prevention or treatment of human disease. The best established and most widely practiced form of cell therapy is the administration of blood and blood products in transfusion medicine. Other emerging applications of cell therapy involve the use of cells as vehicles for the delivery of genes or gene products, as discussed in the section on gene therapy.

In regenerative medicine, cells from various sources are administered to augment, repair, or replace tissues or organs damaged by disease, injury, or congenital anomaly. In this regard, solid organ transplantation can be considered a form of cell therapy. Like blood and blood product transfusion (Chapter 180), solid organ transplantation provides fully differentiated, functioning replacement cells of the transplanted organ (Chapter 48). One of the most important practical limitations of solid organ transplantation is the shortage of available organs relative to the growing demand. In certain forms of irreversible organ system failure, such as neurodegenerative disease, organ transplantation is not a therapeutic option. For these reasons, the development of safe and effective cell therapies is progressing rapidly.

Stem Cells of Human Origin

Stem cells possess two defining properties: (1) the capacity for self-renewal, and (2) the capacity to differentiate into cell types with specialized cellular functions. This may occur at the individual stem cell level through the process of asymmetrical cell division (Fig. 43-1) or at the cell population level wherein a subset of cells differentiate and the remaining stem cells remain dormant or replicate themselves as stem cells. After asymmetrical cell division, non–stem cell derivatives may either generate a pool of organ system–restricted, transit-amplifying cells with enhanced proliferative capacity or differentiate by epigenetic and gene expression profile changes until reaching the terminally differentiated state. This framework was developed after the discovery of bone marrow cells that were capable of reconstituting the adult hematopoietic system. These hematopoietic stem cells constitute the basis for hematopoietic stem cell transplantation, the only form of stem cell therapy currently well established in clinical practice (Chapter 181). Besides these two cardinal properties of self-renewal and differentiation capacity, stem cells can also be classified according to three additional attributes. These are replicative capacity (limited versus unlimited), the scope or potency of differentiation (e.g., pluripotent, multipotent, oligopotent, unipotent), and their place in the life history of the organism (developmental or postdevelopmental). Thus, more recent terminology has broadened use of the term *stem cells* to cover a wider array of cell types that contribute to organ development or have the capacity to repopulate tissues and organ systems. The term *stem cell*, together with the formulations noted previously, has also recently been extrapolated to describe certain cellular subpopulations that may be principally responsible for the growth of malignant tumors. However, because cancer stem cells (Chapter 185) have no role in tissue regeneration, they are not considered further in this chapter.

Embryonic and Induced Pluripotent Stem Cells

The fertilized egg, or zygote, develops first into a blastocyst, then an embryo, and then a fetus. The blastocyst is evident on day 5 after fertilization and consists of 200 to 250 cells, 30 to 34 of which consist of the inner cell mass, or epiblast. The remaining cells are the outer cell mass (Fig. 43-2). After the entire blastocyst attaches to the lining of the uterus, embryonic and extraembryonic development begins. At the blastocyst stage, each cell in the inner cell mass has the capacity to differentiate into derivatives of all three germline layers (ectoderm, mesoderm, and endoderm). In normal development, these cells do not persist beyond the blastocyst stage. Unused preimplantation

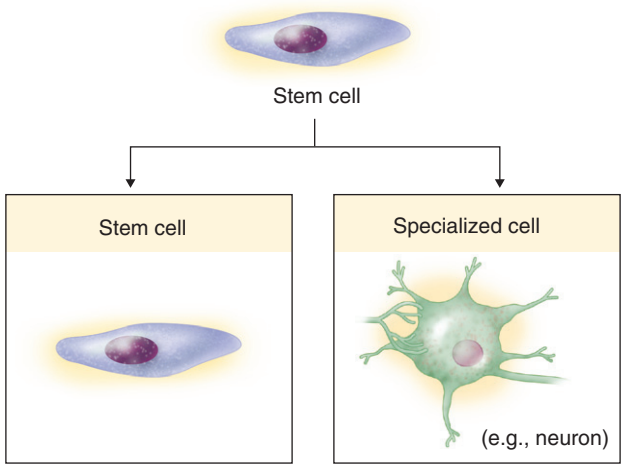

FIGURE 43-1. Asymmetrical cell division. Although this first characteristic was considered a *required characteristic* for stem cells based on their original description in the adult hematopoietic system, not all cell types currently named as stem cells necessarily display this property. For instance, human embryonic stem cells divide by symmetrical cell division.

blastocysts generated for in vitro fertilization can be used to generate human embryonic stem cells (hESCs) from the microdissected inner cell mass. Under appropriate culture conditions, these hESCs exhibit unlimited self-renewal in cell culture in the undifferentiated state without undergoing replicative senescence (i.e., losing the ability to divide). This occurs by virtue of the expression of high levels of the telomerase enzyme, which protects against senescence-associated attrition of the telomeric ends of linear chromosomes during repeated rounds of cell division. Under appropriate cell culture conditions, hESCs are pluripotent; they can differentiate into any of the known cell types of the body.

A major goal of embryonic stem cell research is to direct the differentiation process to enable enrichment to homogeneity of a replacement cell type by adding growth factors that activate cell signaling pathways used in normal embryonic development. This approach has yielded partial enrichment of cells with properties similar to those of authentic fetal pancreatic β cells, vascular endothelial cells, and cardiomyocytes, as well as more mature cells with properties similar to those of bone, connective tissue, and retinal, neuronal, and hepatic cells.

More recently, methods have been developed to reprogram differentiated adult somatic cells into a state of pluripotency, thereby generating induced pluripotent stem cells (iPSCs; Fig. 43-3). The methods to achieve this were enabled by identifying the various cell signaling and gene regulatory pathways that confer pluripotency on hESCs—including the transcription factors Nanog, Oct-4, and Sox-2. The availability of iPSCs from a given patient in need of replacement cells potentially avoids problems of immune rejection because the iPSCs will be recognized as autologous or self rather than allogeneic in origin. In addition, the use of iPSCs appears to invoke fewer ethical concerns, as outlined later. iPSCs derived from patients with certain genetic diseases also provide a unique experimental platform for studying the cellular and molecular pathways that go awry during the development of the affected cell types and tissues.

During the later stages of prenatal human development, cells of fetal origin often show enhanced proliferative capacity as well as the ability to differentiate into more than one type of mature or specialized cell. Thus, these cells have also been used as sources of cell therapy in regenerative medicine and can also be considered stem or progenitor cells—but with more restricted replicative capacity and differentiation potential than is the case for hESCs and iPSCs. To date, the only fetal-derived stem cells that have been used with documented success in human clinical applications are the dopaminergic cells derived from the developing fetal nervous system for the treatment of Parkinson's disease (Chapter 416).

Translating hESCs and iPSCs into a therapeutic platform has the potential for the development of teratomas and malignant tumors from residual undifferentiated cells, following administration of what appears to be a homogeneous population of fully differentiated replacement cells. Progress to clinical trials requires definitive clarification of this concern.

Adult (Postnatal) Stem Cells

After birth, many tissues are thought to contain a subpopulation of cells with the capacity for extended self-renewal, combined with the ability to differentiate into more mature cell types with specialized functions. Adult stem cells generate an intermediate state characterized by enhanced proliferation (transit-amplifying cells or progenitor cells), before reaching full terminal differentiation (Fig. 43-4).

Adult stem cells, thought to represent less than 0.01% of the total number of cells, are located in specialized supportive niche compartments at various sites within the hematopoietic system and elsewhere, and respond to cues in their local microenvironment. As a result of the success of hematopoietic stem cell transplantation in the treatment of bone marrow failure or in conjunction with myeloablative therapy in malignancy, scientists have been motivated to find adult stem cells in other organs and other organ systems. Adult tissues and organ systems reported to contain stem cells include bone marrow (hematopoietic and mesenchymal compartments) and peripheral blood, the central nervous system, blood vessel endothelium, dental pulp, epithelia of the skin, adipose tissue, digestive system, cornea, retina, testis, and liver. Controversy exists regarding the existence of adult stem cells in the kidney, pancreas, and heart. Whether adult stem cells represent remnants of developmental stem cells that persist into adulthood for purposes of organ maintenance and repair or represent a distinct cell type dedicated for this latter purpose is not clear.

Given their low percentage, dispersed tissue distribution, and markers that are not fully defined, isolation of adult stem cells for therapeutic use has been technically challenging, with the greatest successes to date reported for mesenchymal stem cells. Mesenchymal stem cells represent a type of multipotential adult progenitor cell found in the bone marrow niche that supports hematopoiesis. Mesenchymal stem cells have also been isolated from adipose tissue, blood, umbilical cord, and muscle. Although mesenchymal and other multipotential adult progenitor cells have been shown in some experimental animal models to differentiate into a wide variety of cell types representing all three germ layers, they do not possess the capacity to develop into every cell type, as do hESCs and iPSCs.

There is some evidence that beyond the therapeutic value to hematopoietic reconstitution, bone marrow transplantation may also make some contribution to restoration of organ system function after certain forms of solid organ transplantation. Although adult stem cells are classically thought to be committed to a narrow spectrum of differentiation within the organ system, some studies have suggested the possibility that certain adult stem cells may display unexpected degrees of plasticity. *Plasticity* refers to the ability of differentiated cells to undergo transdifferentiation into mature cell derivatives of another germline origin. Such plasticity would allow bone marrow-derived hematopoietic or mesenchymal stem cells to transdifferentiate into cardiac, vascular endothelial, connective tissue, neuronal, or other cells that show promise in clinical trials of regenerative medicine.

Like iPSCs, postnatal or adult stem cells have the potential to circumvent two of the obstacles in developmental stem cell therapy: ethical concerns regarding the use of cells of developmental origin, and alloimmunologic rejection. Adult stem cells may have the additional advantage of being less prone to teratoma and tumor development. hESCs and their derivatives generally emanate from a source not related to the potential recipient and can therefore be considered an allogeneic graft. Research studies have confirmed the immunogenicity of hESCs despite their very early developmental origin. Adult stem cells and iPSCs of autologous origin should not elicit an alloimmunologic response and therefore offer a potential solution. On the other hand, when the underlying disease is an active autoimmune destructive process (e.g., type 1 diabetes mellitus), it can be expected that replacement cells of autologous origin might also be targets of the immune-mediated pathophysiologic process.

Specific Disease Applications in Cell Therapy

Except for hematopoietic stem cell and solid organ transplantation, experimental cell therapies have been implemented in a limited number of patient trials.

Neurodegenerative Disease and Neuronal Injury

Parkinson's disease (Chapter 416) involves loss of melanin-containing dopaminergic neurons within the substantia nigra pars compacta of the midbrain, coupled with accompanying depletion of striatal dopamine. This cellular loss is responsible for the major motor features of the disease. Although

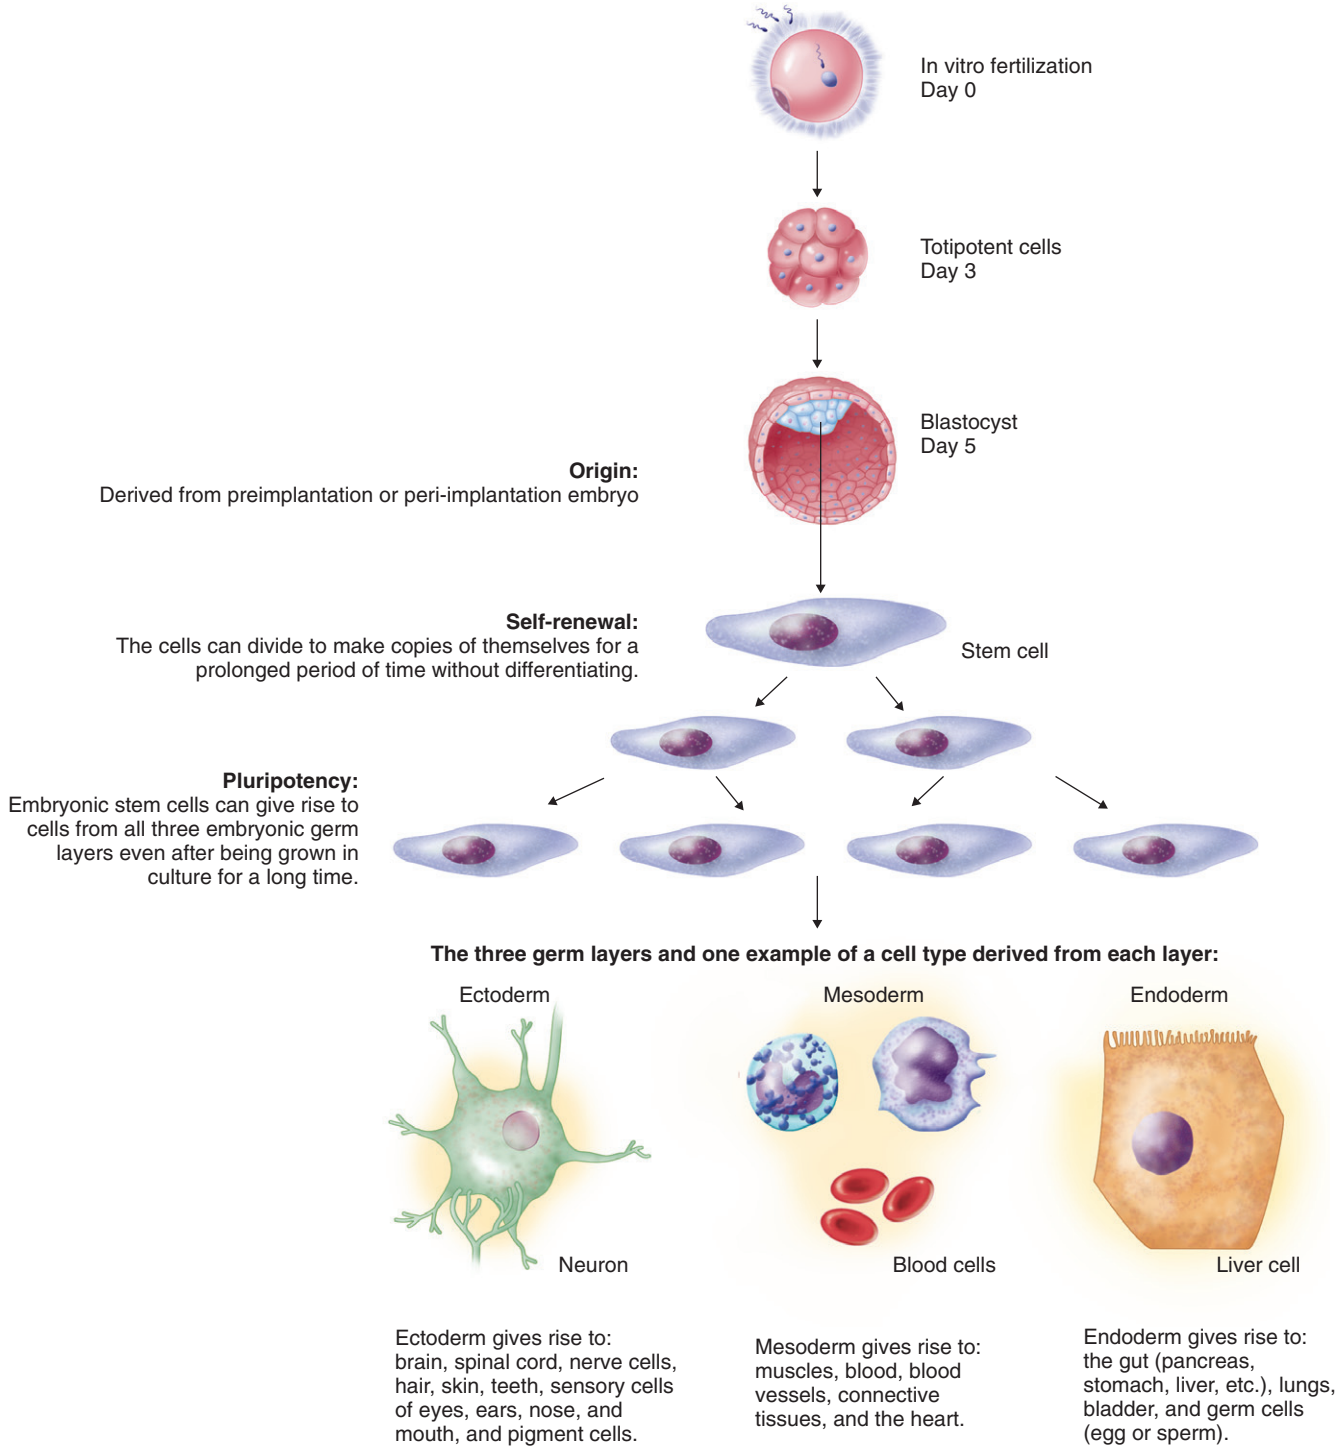

FIGURE 43-2. Embryonic stem cells. *Totipotency* refers to the capacity to differentiate into all cell types in an organism, including extraembryonic tissues, placenta, and umbilical cord, a property confined to the fertilized egg itself, including the cells derived from the first few cell divisions after fertilization. *Pluripotency* refers to the capacity to differentiate into all the specialized cell types derived from the three germ layers (ectoderm, mesoderm, endoderm) of the developing embryo and is a hallmark feature of embryonic stem and germ cells.

pharmacologic dopaminergic replacement therapy is effective in the early stages of illness, prolonged treatment with pharmacologic agents alone is associated with refractoriness and complications and fails to halt the underlying neurodegeneration. In the search for more definitive therapy, early reports of cell replacement suggested significant improvement in motor function after intrastriatal implantation of mesencephalic tissue, obtained from aborted human fetuses aged 6 to 9 weeks after conception. Long-term immunosuppressive treatment is essential to allow transplanted dopaminergic neurons to develop into their full functional potential despite the notion of an immunologic sanctuary within the brain. Clinical assessment standards have provided evidence of long-lived graft survival and clinical benefit after therapy with cells of fetal origin that has now lasted up to 10 years or longer in some patients. Further progress is limited by lack of sufficient source tissue to treat a large number of affected patients, prohibitive variability in functional outcome, reports of serious dyskinesias in a subset of treated patients, and ethical considerations.

Investigations of stem cell–based approaches for the treatment of other neurodegenerative diseases, including Alzheimer's disease, Batten's disease, amyotrophic lateral sclerosis, stroke, and brain and spinal cord injury, are now moving between experimental animal model studies to planning of clinical trials. Recent reports have shown a major clinical benefit in animal models on directed differentiation and transplantation of hESCs toward a retinal pigment epithelium. Human studies with these cells may be soon initiated for patients suffering from age-related macular degeneration.

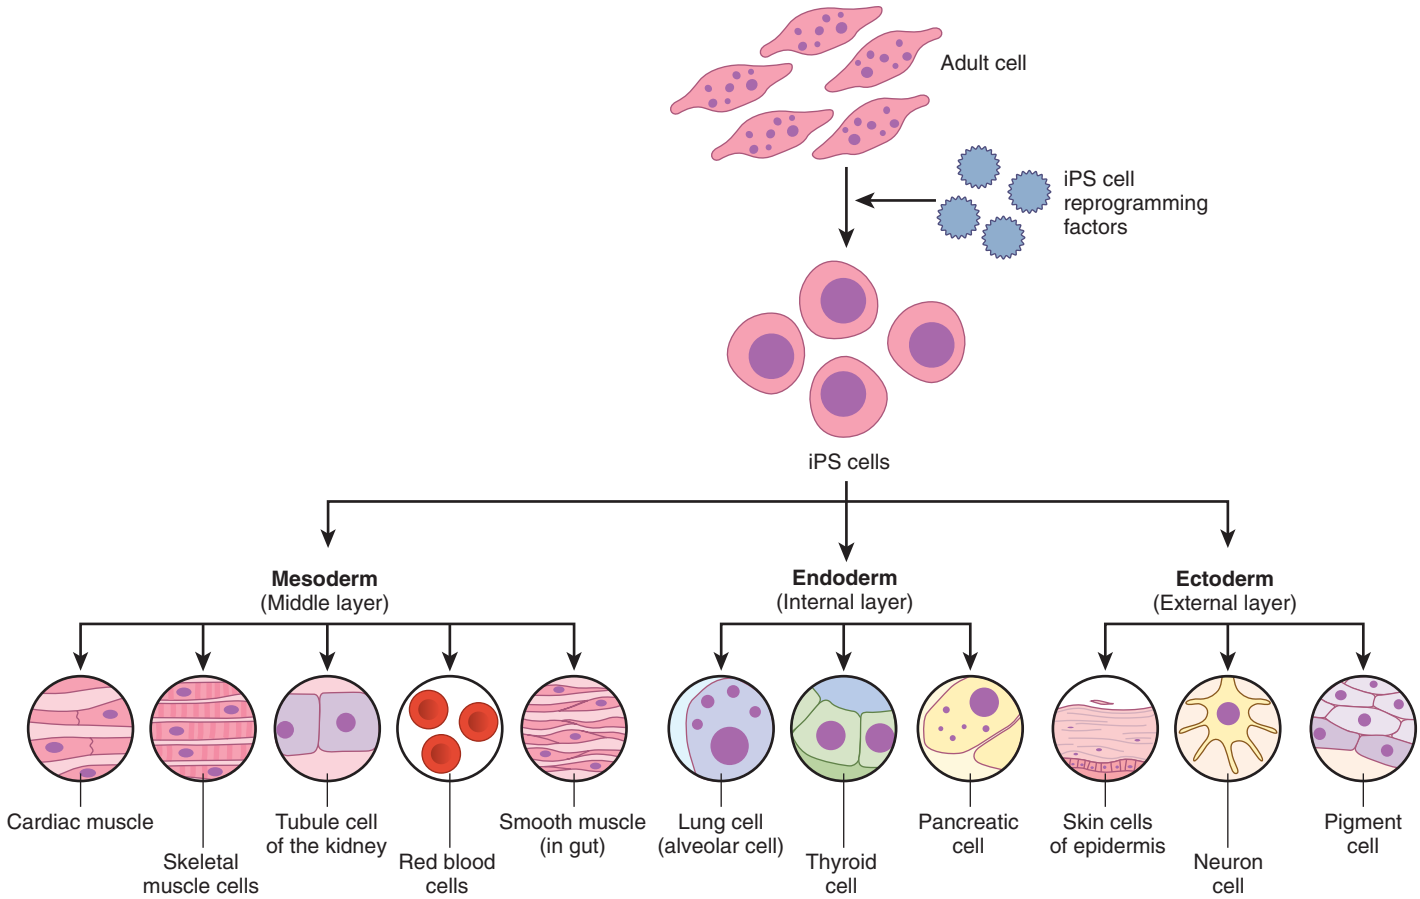

FIGURE 43-3. Induced pluripotent stem (iPS) cells. Introduction of three growth factors and a chemical agent that modifies gene expression is sufficient to restore pluripotency to adult somatic cells. (Adapted from http://www.sigmaaldrich.com/life-science/stem-cell-biology/ipsc.html.)

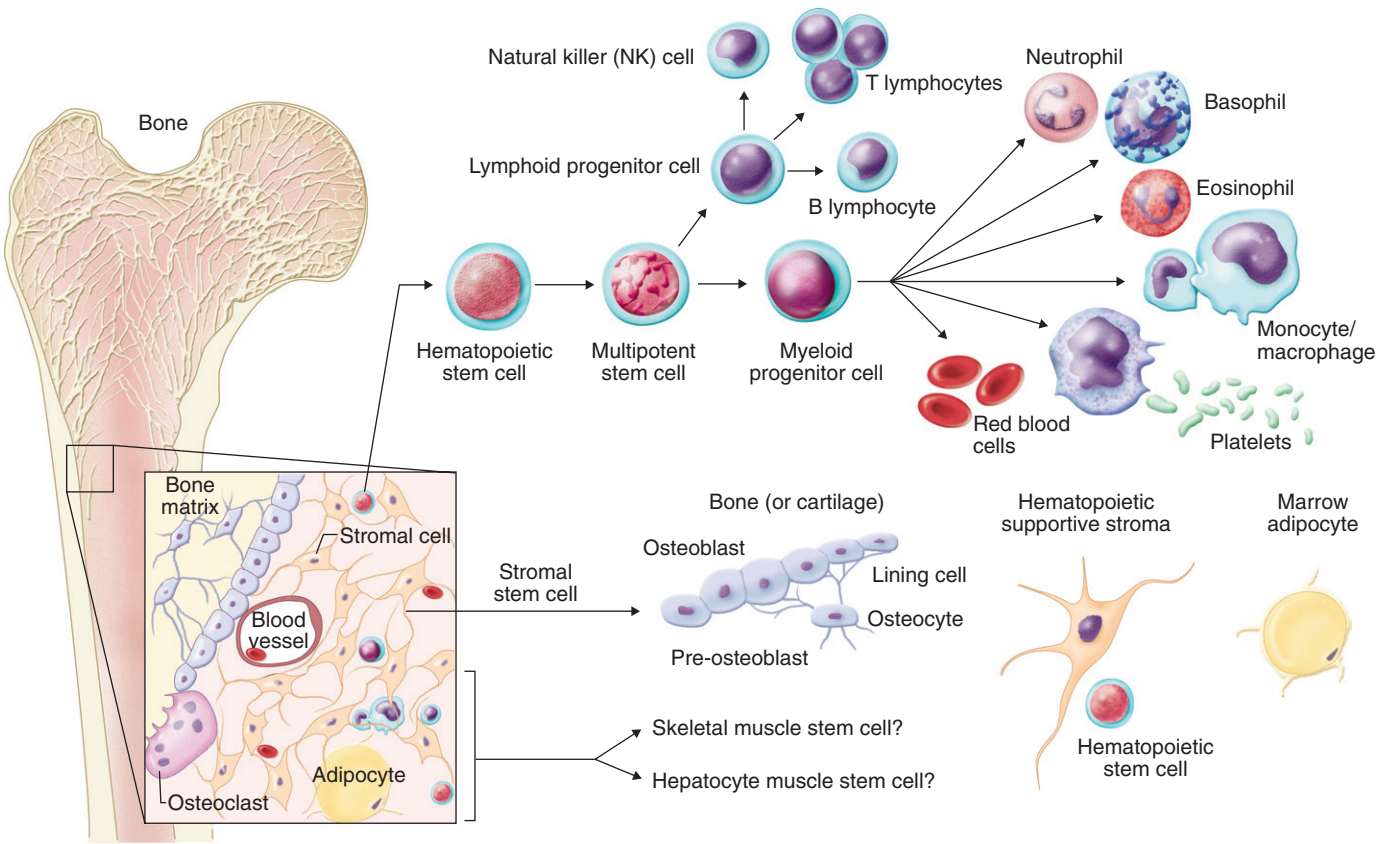

FIGURE 43-4. Adult stem cells. Adult stem cells can be multipotent and have the capacity to differentiate into a limited number of different cell types, often restricted to a given tissue or organ system, as in the case of adult hematopoietic or epidermal stem cells. Two stem cell types have been isolated from adult bone marrow—the hematopoietic stem cell and the mesenchymal stem cell. Adult mesenchymal stem cells of bone marrow origin, although their range of differentiation has been shown to be broader than that of any other adult stem cell type, do not reach pluripotency. It is thought that in some organ systems, such as the gastrointestinal epithelium, a unipotent pool of progenitors exists for repopulating a rapid population turnover of only one type of cell—although it is difficult to be certain whether such progenitors can be distinguished from the overall population of fully differentiated cells in tissues with high cellular turnover.

Muscular Dystrophies and Other Disorders of the Musculoskeletal System

In the major genetic forms of muscular dystrophy (Chapter 429), a range of approaches have been developed that aim to correct the genetic defect, restore functional expression of the missing gene product (e.g., dystrophin), and thereby slow disease progression. Implantation of myoblast muscle precursor cells might enable the improved repopulation of degenerating dystrophic muscles in these disease states. Although initial success in harvesting myoblasts was reported, clinical benefit did not ensue because of an inflammatory response that destroys most injected myoblasts. Furthermore, failure of myoblasts to migrate meaningful distances from the injection site renders implantation by direct needle injection impractical in acute muscular dystrophy disorders.

Protocols have been devised for the development of mixed biomechanical substitutes for bone, tendon, cartilage, and other connective tissues that incorporate or produce relevant surrounding matrix. For these forms of cell therapy, connective tissue scaffold can be produced in vitro and then repopulated with endogenous recipient cells in the patient, thus potentially preempting immune rejection and other problems related to the presence of cells of allogeneic origin.

Heart Disease

In heart failure (Chapters 58 and 59), limitations of clinical therapy have motivated the search for cell-based therapies to restore or augment myocardial contractile function or reestablish functional cardiomyocytes in damaged cardiac regions.

Autologous skeletal myoblasts have been shown in clinical trials to grow in scarred cardiac tissue after direct intracardiac injection. However, histologic or functional evidence of electrical or mechanical coupling has not been demonstrated. Currently, most experimental work selects a specific preparation of bone marrow and peripheral stem cells and progenitors. In some cases, the apparent differentiation of bone marrow cells into cardiac myocyte phenotypes has been subsequently refuted. In cell culture, hESCs are easily induced into a cardiomyocyte phenotype, including the following features: rhythmic contraction, gene and protein expression markers for cardiomyocyte differentiation, electrical coupling through gap junctions, responsiveness to chronotropic and inotropic agents, and electromechanical coupling with heterotypic cardiomyocytes derived from other sources. Cardiomyocytes of human embryonic stem cell origin have been shown to serve as a biologic pacemaker after conduction system ablation in experimental animals. They have also been shown to enhance cardiac contractility after myocardial infarction induced by coronary ligation in experimental animals. For the treatment of refractory cardiac rhythm disturbances, a combination of cell and gene therapy involves the stable expression of potassium conductance or other ion channels in skin fibroblasts derived from patients suffering from refractory rhythm disturbances, followed by their implantation into electrically unstable regions of the heart by guided endomyocardial injection. A major experimental effort in the use of bone marrow–derived cells through intracoronary administration aims to improve left ventricular function after acute myocardial infarction. Clinical experience with more than 1000 patients who received stem cell therapy indicates a favorable safety profile with a modest improvement in cardiac function and structural remodeling in the setting of acute myocardial infarction or chronic heart failure. Direct intracardiac muscle administration was more frequently associated with lesser degrees of improvement and sometimes with arrhythmias.

Diabetes Mellitus

Successful pancreatic transplantation and improved glucocorticoid-free protocols for transplantation of islets of Langerhans have been shown not only to restore glucose control in patients with diabetes mellitus but also to prevent or even reverse some of the disease's complications (Chapters 236 and 237). However, whole organ or islet-based transplantation approaches are limited both by immunologic rejection and by limitation of an available source of transplantable tissues. This has motivated the search for cell types that can replace (type 1 diabetes mellitus) or augment (type 2 diabetes mellitus) deficient β-cell function. Although no clinical applications have been reported, significant progress has been made with cells of human origin tested in cell culture and in animal models. Strategies that have been pursued include the developmental reprogramming of hepatic cells along the endocrine pancreatic lineage differentiation to provide these cells with the appropriate machinery for glucose-mediated insulin release. Protocols have also been established for differentiation of hESCs to either a precursor or mature β-cell phenotype. Because the pathogenesis of type 1 diabetes mellitus involves autoimmune destruction of pancreatic islet cells, the β cells derived from autologous sources, such as the patient's own iPSCs, might also become a target for autoimmune destructive processes unless preemptive measures are taken. In addition, because glucose monitoring and insulin delivery systems are constantly improving, any cell therapy–based approach must provide a clear advantage over existing therapeutic modalities while meeting the most rigorous standards of patient safety.

Stem Cell–Derived Platforms in Gene and Drug Discovery

In addition to the generation of cells for regenerative applications, the ability to grow a wide variety of different specialized cell types of human origin in culture provides unparalleled opportunities for gene and drug discovery and testing. For example, the ability to grow human cardiomyocytes in culture provides a preclinical human cellular-based experimental platform for screening newly developed drugs in terms of their potential to cause QT-interval prolongation and hence the risk for arrhythmia in the clinical setting. Other examples include the creation of an experimental tissue microenvironment of human origin for studying the stromal response to tumor growth and testing anticancer drugs that target tumorigenic responses such as angiogenesis. By combining technologies such as RNA interference (RNAi) with human stem cell growth and technology (E-Fig. 43-1), it will also be possible to uncover the role of certain gene products in the biochemical pathways and cellular responses in gene therapy.

Societal, Ethical, and Legal Considerations in Stem Cell Research and Therapy

Societal, ethical, and legal concerns about defining the concept of personhood status before birth have emerged among countries and political or religious constituencies in the field of stem cell research and therapy. Although there is a broad consensus that full personhood sanctity and associated rights should be accorded to each individual from at least the moment of birth, similar consensus does not apply to the status of an individual before birth. Various guidelines for research have been developed worldwide based on milestones in embryonic development. Bioethicists and legislators are often concerned about the possibility that research scientists and clinicians will move beyond allowable activities into prohibited domains. Previous concerns about therapeutic cloning, in which the first step is oocyte somatic nuclear transfer, or replacement of the haploid nucleus of a harvested oocyte with the diploid nucleus derived from the somatic cell of a potential cell therapy recipient were based mostly on the fear of a slippery slope to reproductive cloning. However, the successful generation of human iPSCs has for the most part supplanted the incentive for oocyte somatic nuclear transfer. Continued civil discourse and strict regulatory guidelines to ensure patient safety in clinical trials will remain key in resolving the bioethical dilemmas and societal concerns raised by stem cell and related emerging biomedical technologies.

GENE THERAPY

The use of genes as therapeutic platforms emerged during the mid-20th century, and in the 1990s, the first regulated registered studies were performed in the United States. Since then, more than 10,000 patients have been treated in more than 1000 studies in 15 countries across all continents with various modalities of gene therapy for a variety of diseases. About 50 studies have been performed for tracking gene delivery and more than 1000 for therapeutic assessment. One hundred studies involved monogenic diseases, and 1000 involved cancer patients, which is also the most common disease category for gene therapy studies worldwide. Two gene therapy agents are currently available on the market. Fomivirsen (Vitravene) is used for the treatment of cytomegalovirus retinitis (Chapter 384) in patients with acquired immunodeficiency syndrome (AIDS). The *p53* tumor suppressor coding sequence in an adenovirus vector is used for the treatment of head and neck cancer patients and is registered only in China. Most patients who participated in the first gene therapy clinical trials were administered marker or reporter genes rather than actual therapeutic genes. Of the thousands treated, two deaths have been attributed directly to gene therapy. The mortality statistics attributed to gene therapy are very low when compared with those associated with chemotherapy and transplantation, two therapeutic modalities frequently used today in clinical practice for disease targets of gene therapy.

Genetic Material

The therapeutic payload in most cases, the core of every gene therapy drug, is composed of an expression cassette. Essential clinical objectives of gene therapy are based on controlling gene expression through regulation of a tissue-specific promoter for expression. Although a few systems have been developed in the experimental setting, none has yet received approval for clinical use by the U.S. Food and Drug Administration or any other regulatory authority, other than the expression of *p53* in head and neck tumors by regulatory authorities in China.

Gene Therapy Delivery Methods

Gene therapy agents are often composed of two elements: the genetic material and the delivery system. The latter is usually the more complex and limiting component, and it is important to select the most efficient delivery method for any genetic therapy. Unfortunately, many gene therapy delivery methods are associated with potential adverse effects, thus necessitating tailoring of therapy to specific clinical considerations. The most commonly used delivery systems have used retrovirus- and adenovirus-based approaches. Virus-based approaches take advantage of the fact that viruses have been designed through evolution to serve as genetic material delivery systems. However, for each specific virus-based gene therapy vector, there have been major disadvantages that should be balanced against potential therapeutic benefits. Nonviral methods have also been used in many studies. The most commonly used nonviral delivery methods involve the use of naked/plasmid DNA and liposome-mediated delivery. In cancer gene therapy, the immune response to the delivery vehicle carrying the anticancer genetic material can be used to advantage by serving as an adjuvant. However, the system for delivery of a gene to be expressed for a prolonged period to replace or supplement a missing gene product in monogenic disease states should preferably be ignored by the immune system.

Naked/Plasmid DNA

In theory, the most straightforward approach to gene therapy would be the introduction of genetic material, such as an antisense molecule, short interfering RNA (siRNA), or an expression cassette, directly into the targeted cellular compartment (i.e., DNA into the nucleus or RNA into the cytoplasm). However, in clinical practice, this turns out not to be efficient. Systemic administration of naked DNA into the blood stream generally results in loss of the delivered genetic material, nonspecific interactions with serum proteins, and active degradation mediated by the innate immune system (e.g., tissue macrophages). Direct administration or application to target organs or tissues may circumvent some of these problems, but certain barriers must also be overcome. When the payload is a DNA expression cassette, it will need to interact with the cellular membrane and penetrate it, escape the endosomal compartment and cytosolic degradation by nucleases, and traverse the nuclear pores to reach the nucleus of the cell. This is a long process that is prone to failure unless supported by additional means that allow the DNA to pass the cellular barriers. Electroporation is an approach that has been applied to well-circumscribed body compartments or masses, such as muscle, skin, and tumors. Patients treated with electroporation have experienced tissue damage and associated pain. Additional methods have also been developed for the administration of naked DNA, including the different types of gene guns used for DNA vaccination and ultrasound energy for the transduction of endothelial cells, which could be used for cardiovascular applications and against tumor angiogenesis.

Naked DNA has also been formulated as part of DNA vaccination approaches to the treatment of cancer and immune and infectious diseases. Although preclinical studies have been promising, successful extrapolation to the clinic has not yet been achieved.

Nonviral Vectors

Nonviral vectors have been designed to overcome the cell membrane barrier and, in some cases, intracytoplasmic compartmentalization of the administered genetic material. These nonviral vectors are efficient at enhancing membrane penetration in vitro; however, their efficiency in vivo is significantly reduced. There are additional advantages to nonviral delivery systems: they are inexpensive and can carry large DNA molecules, and their structure can be modified to comply with specific needs, such as conjugation to short peptides for targeting. After systemic and, in some cases, local administration, these nonviral vectors stimulate the innate immune response by serving as adjuvants. They interact with serum proteins as well as cells that were not meant to be targeted, and with extracellular matrix. Once the DNA reaches the nucleus, it is subject to silencing. After cell division, expression is significantly reduced. Currently, nonviral vectors are used in specific selected cases. Local and systemic delivery of nonviral delivery systems could induce reciprocal immune effects with an undesirable inflammatory clinical response.

Adenovirus as a Viral Vector

Adenovirus is a nonenveloped DNA virus with the capacity to carry a large genetic payload. Adenoviruses, as well as adenovectors (the virally based vector), transduce nondividing cells, a property that is important for gene therapy for many cell types, such as hepatocytes (<0.1% of hepatocytes are replicating in humans at any given time). These vectors have been modified to prevent their replication in healthy tissues. Replication-defective (RD) adenovectors are used for short-term expression. Additional modifications of the viral genome and the cellular system supporting production of the viral particles have enabled deletion of all the viral coding sequences, thereby converting it into a "gutted" vector (helper-dependent [HD] adenovector). It is possible to clone the therapeutic genes into the RD adenovirus and generate recombinant adenovectors in a relatively short time. An additional advantage of adenovectors is that the relatively simple production system enables the generation of a very high titer. High viral titers are essential when administration is parenteral or when production of a large amount of a given protein is needed, such as in disease states in which secretion of a protein is impaired and each cell needs to encode its own normal protein. The HD adenovectors, which do not harbor virus-encoded genes, are able to support the transgene expression for months and possibly for more than a year. RD adenovector-transduced cells express viral proteins and induce an immune response. They are thus used in clinical cases in which the therapeutic gene needs to be expressed at high levels for a short period. High-titer systemic administration of adenovectors could be associated with severe adverse effects, such as disseminated intravascular coagulopathy (Chapter 178).

Retroviral Vectors

Retroviral vectors are an RNA group of viruses that harbor two RNA genomic copies in each viral particle, which is composed of a capsid and surrounded by an envelope. For gene therapy applications, two groups of viruses have been modified for clinical assessment and use: the oncoretroviruses and the lentiviruses. Vectors generated from both groups have already entered clinical testing.

Gammaretroviral Vectors

Gammaretroviral vectors are derived from different gammaretroviruses, including the murine leukemia virus and the Moloney murine leukemia virus. RD viruses are produced in special packaging cells that supply all the essential components in *trans* for viral replication and structural proteins. The viral gene therapy vector is composed of (1) a genome without any encoded viral sequences that is responsible for the production of viral proteins; (2) the therapeutic genetic payload and the structural components; and (3) the capsid and envelope. These viral vectors can carry transgenic payloads up to 8 kilobases (kb) in length. Retroviral vectors are capable of transducing only dividing cells. If the DNA reaches the nucleus, integration of the viral genome into the host cell chromosome can occur and lead to stable, long-term transgene expression. At its peak, a multiplicity of infection (MOI) integration occurs at numerous sites. Therefore, if long-term correction of a genetic disorder is required, the target cells must first be induced to replicate. The integration is a random event, with preference within an approximately 5-kb nucleotide window around the transcription initiation site. Thus, there is concern that interference with normal cell function could occur, including the activation of oncogenes or the disruption of tumor suppressor genes. Such events have occurred and have led to the development of malignant transformation both in animal models (rodents and primates) and in humans. There is evidence that "young" cells of the hematopoietic system and hepatocytes are more susceptible to malignant transformation than are terminally differentiated cells. On the other hand, the selectivity for dividing cells is advantageous if one aims to deliver a toxin gene to a growing tumor surrounded by quiescent normal parenchyma. The production of retroviral vectors is less efficient than that of adenovectors. As a result, the application of retroviruses is, in most cases, not by systemic administration but by ex vivo or direct injection into normal or tumor tissue.

Lentiviral Vectors

This group of viruses has been developed more recently for gene therapy applications. Human immunodeficiency virus (HIV) and the feline, simian, and equine immunodeficiency virus (FIV, SIV, and EIV, respectively) lentivirus family members were converted to become lentivectors for gene therapy. These vectors are deprived of the structural and most nonstructural and accessory genomic sequences that are supplied in *trans* in the packaging cell line for vector production. In addition, the envelope glycoprotein is of nonlentivirus origin, and for safety measures, the origin of replication is inactivated to generate a self-inactivating vector. All these genomic manipulations have been introduced to improve the safety of the lentivector and to enable a large cloning capacity of up to 8 kb. The lentivectors have been applied in only a few gene therapy studies, mainly for the treatment of AIDS patients. However, additional studies using lentivirus-based delivery systems are under way in patients with hemoglobinopathies, Parkinson's disease, X-linked adrenoleukodystrophy, and other genetic and degenerative diseases, with promising results. The long-term risk of using retroviral vectors, including gammaretroviral and lentiviral vectors, is not known. The possible development of clonal dominance, transformation, and cancer in the case of retroviral stem cell transduction is judiciously monitored in all appropriately registered studies.

Adenovirus-Associated Virus

Adenovirus-associated virus (AAV) is a single-strand DNA, nonenveloped, nonpathogenic human parvovirus. Viral vectors were derived from several serotypes, which exhibit different tissue and cell tropism. The capacity of AAV vectors is smaller, which is a limitation for certain AAV vector gene therapy approaches. The capacity for high titers (10^{12} transducing units per milliliter) of AAV serotypes enables systemic injections with reasonable MOI in targeted cells and tissues. Additional advantages of AAV vectors are that they transduce nondividing cells and do not integrate into the target cell genome. The innate immune system detects the AAV and responds to it, and antibodies generated against the viral capsid after a single injection attenuate the effect of a second administration of AAV vector. Long-term expression is detected with the use of AAV vectors. Phase I to III clinical studies have assessed the AAV vector for genetic, viral, inflammatory, degenerative, and malignant diseases. A study with AAV coagulation factor IX showed short-term efficacy owing to the development of an immune attack against the transduced hepatocytes. Studies both in Europe and the United States have shown a long-term benefit for patients with Leber's congenital amaurosis treated by subretinal administration of AAV to express retinal pigment epithelium-specific 65-kD protein (RPE65). Success was also reported in Parkinson's disease. Furthermore, more than 2 years of follow-up showed no significant side effects.

Special Virus-Derived Vectors

In addition to the adenoviral, retroviral, and AAV vectors, numerous, more specialized virus-based vectors with interesting properties and clinical objectives have been developed during the past 10 years.

Herpes simplex virus type 1 (HSV-1) is a DNA virus that can be manipulated to become RD and accommodate a large amount of foreign DNA for gene delivery. Expression of the transgene payload is transient. The HSV-1 amplicon has been used in numerous clinical trials of gene therapy for neurologic diseases.

Virus-like particles (VLPs) were recently developed for vaccination or gene therapy. VLPs of human papillomavirus were recently used as empty particles for vaccination against cervical cancer with significant success. Viruses of the same group, including SV40, which is also a DNA virus, are used for the generation of VLPs to carry gene therapy payloads. One advantage of SV40 is the low immune response against the virus. Again, similar barriers will slow the development of these vehicles, such as limitation of titers and production capacity.

Recombinant vaccinia virus (rVV) was initially developed for the expression of proteins in transduced tissues. Clinical studies in this avenue have encountered limited success. However, recent development of rVV for the treatment of malignant diseases through the expression of antigens might yield clinical benefit.

Oncolytic Viruses

Oncolytic viruses replicate in tumor cells and induce a cytopathic effect or kill tumor cells through other means, such as induction of apoptosis. The major obstacle facing the current development of antitumor drugs is not their potency, but rather their low selectivity for tumor cells. High therapeutic selectivity is essential to enable a safe therapeutic window. Virotherapy has such properties, but these viruses are still waiting to be proved clinically effective. Tumor-targeted oncolytic viruses are composed of two groups. Genetically engineered viruses are designed to replicate in tumor cells preferentially. This group includes adenoviruses that can replicate only in the presence of a nonfunctioning tumor suppressor gene, such as *p53* or *Rb*. The latter viruses will selectively replicate in tumor cells and induce their killing. The engineered HSV-1 and rVV viruses can also be included in this group. The second group consists of inherently antitumor-selective viruses found to possess antitumor effects through specific protein expression (reovirus) or viruses that activate the innate or adaptive immune response against the tumor, such as the Newcastle disease virus, measles virus strains, Sindbis virus, poliovirus, and vesicular stomatitis virus. The rationale for the use of reovirus in a virotherapeutic approach against cancer is based on the observation that reovirus infection activates host protein kinases to shut down protein production, an essential protection against the infection. Activated Ras signaling is known to interfere with protein kinase activation and with its signaling after reovirus infection. This allows the reovirus to continue to replicate in tumor cells and spare normal tissues. Such replication induces a specific cytopathic effect in malignant cells. Genetically engineered viruses and inherently antitumor-selective viruses have been tested in early clinical trials and are awaiting studies to determine their effectiveness in specific types of cancer. Virotherapy, in combination with standard chemotherapy, has the potential to further increase the antitumor activity of oncolytic virotherapy in a synergistic manner.

Diseases Treated by Gene Therapy

Inherited Immunodeficiency

More than 30 patients reported to date worldwide have undergone treatment with different retroviral vectors for inherited immunodeficiencies (Chapter 258). Patients with one of the following three diseases are included in this group: two types of severe combined immunodeficiency (SCID), both of which are characterized by dysregulation of lymphocyte development, and X-linked chronic granulomatous disease (X-CGD), an inherited immune deficiency with absent phagocyte reduced nicotinamide adenine diphosphate (NADPH) oxidase activity caused by mutations in the *gp91* (*phox*) gene. Individuals with adenosine deaminase (ADA) SCID suffer from premature death of T, B, and natural killer (NK) cells as a result of the accumulation of purine metabolites; patients with this condition have been treated with vectors expressing the *ADA* gene. In the first patients with ADA SCID, transduced T cells expressing transgenic *ADA* have been shown to persist for longer than 10 years; however, the therapeutic effect of gene therapy resulted in incomplete correction of the metabolic defect. More recently, an improved gene transfer protocol of bone marrow CD34-positive cells, combined with low-dose busulfan, resulted in multilineage, stable engraftment of transduced progenitors at substantial levels, restoration of immune function, correction of the *ADA* metabolic defect, and proven clinical benefit. Overall, no adverse effect or toxicity has been observed in patients treated with *ADA* gene transfer in mature lymphocytes or hematopoietic progenitors.

The X-linked type (X-SCID group), in which there is defective cytokine-dependent survival signaling in T and NK cells, was shown to be corrected by introduction of the wild-type sequence of the common γ-C chain, which is an essential component of five cytokine receptors. In one clinical study, hematologic malignancies developed in four patients. One of the four died of this complication. A group of ten patients treated with a different viral transduction protocol were successfully treated, with one reported malignancy in up to 8 years of follow-up. Two adult X-CGD patients who suffered recurrent bacterial infections have been treated with CD34-positive cells transduced with a gammaretroviral vector expressing *gp91 phox*, with significant clinical improvement in the short term. However, in both of these patients, there was an expansion of gene-transduced cells caused by the transcriptional activation of growth-promoting genes leading to myelodysplasia and gradual loss of efficacy.

In summary, of the close to 30 patients worldwide treated with gene therapy for immunodeficiency disorders, significant clinical improvement has been observed in many. However, severe and even life-endangering adverse consequences have been encountered with certain viral vectors and protocols. Additional clinical information from long-term observation and new clinical studies will be important for a clearer assessment of clinical benefit.

Hematologic Disorders

Additional inherited diseases treated in recent years with gene therapy have included mostly hematologic conditions in which a low amount of a secreted protein could reverse the clinical phenotype, and partial success has been achieved in various inherited bleeding disorders. However, the response has not usually been sustained or has been accompanied by adverse reactions, such as increases in hepatic enzymes in the case of hepatic artery administration.

Cardiovascular and Pulmonary Conditions

The most common cardiovascular-related syndromes are related to atherosclerotic arterial occlusive disease. To overcome arterial occlusions, especially when conventional treatments fail to improve blood supply to the ischemic organs, therapeutic angiogenesis has been advocated as a therapeutic option. Transfer of genes encoding angiogenic growth factors (vascular endothelial growth factor and fibroblast growth factor), delivered by nonviral and viral vectors, has been tested in phase II and III studies in patients with coronary and peripheral arterial disease.

Cystic Fibrosis

Experimental protocols for gene therapy for cystic fibrosis (CF) (Chapter 89) have been implemented since 1990. The cystic fibrosis transmembrane conductance regulator (CFTR) protein is mutated in patients with CF. Transducing the epithelium of the nasal and bronchial tree is potentially feasible through nonsystemic approaches. Nonviral gene therapy methods that deliver a copy of the *CFTR* gene to the airway of CF patients have been developed. Several placebo-controlled clinical trials of liposome-mediated *CFTR* gene transfer to the nasal epithelium have confirmed its safety and demonstrated variable degrees of functional correction.[1] In addition, several clinical studies have assessed the potential of retrovectors, adenovectors, and AAV vectors for gene therapy for CF.[2,3] With both nonviral and viral delivery systems, there were only mild side effects. However, the long-term clinical benefit has been marginal. Improved vectors are being assessed in preclinical studies.

Cancer

Gene therapy approaches to treatment of cancer have been based on perturbation of pathways in the tumorigenesis process (Chapter 185), which has led to diverse anticancer gene therapy approaches.

Tumor-Specific Expression of Anticancer Proteins

Certain promoters are activated in many types of tumors (e.g., human telomerase or survivin), whereas others are activated in specific types of tumors (probasin in prostate cancer, ceruloplasmin in ovarian cancer, HER2 in breast cancer, carcinoembryonic antigen in colon cancer). Targeting of tumor-specific promoters constitutes a rational basis for anticancer therapeutics, which may fall into different categories, including cellular proteins that are involved in apoptosis or antiproliferation, or both (e.g., p53, Fas, p202, E1A, and BAX). Their expression induces tumor-specific killing. The most clinically advanced gene therapy drug against cancer is the RD adenovector expressing the human *p53* gene. This therapy (Gendicine) is approved in China for the treatment of patients with head and neck squamous cell carcinoma by direct administration into the tumor bed. According to the results emanating from China[4] and clinical phase III studies in the United States, this treatment has therapeutic benefits. Additionally, the use of suicide genes is one of the most promising approaches for cancer gene therapy.

DNA Vaccines

Human clinical trials using DNA vaccines against cancer (as well as infectious diseases) have been conducted in the past several years. Although these studies have consistently demonstrated the safety of such DNA vaccines, the resultant immunologic responses have not been encouraging, including lack of or low antibody response detected in most cases and somewhat weak cellular response in some trials. Disappointing results were also reported with the use of DNA vaccines against HIV and other infectious agents. However, new methods are currently being assessed for DNA vaccination, such as electroporation and new generations of gene guns. Tumor gene knockdown has been used in many different clinical studies. This approach involves the use of antisense oligonucleotides (ASOs) to target genes involved in cancer progression. ASOs inhibit translation through a mechanism that involves the formation of an mRNA-ASO duplex, which leads to RNase-H-mediated cleavage of the target mRNA. The disappointing lack of clinical efficacy for some first-generation ASOs indicates that challenges remain to be confronted and overcome.

RNA Interference

RNA interference regulates gene expression by a highly precise mechanism of sequence-directed gene silencing at the stage of translation by degrading specific messenger RNAs or by blocking its translation into protein. Research into the use of RNAi for therapeutic applications has gained considerable momentum. It has been suggested that many of the novel disease-associated targets that have been identified are amenable to conventional small molecule drug blockade and can potentially be targeted with RNAi. In the coming years, the concept of RNAi will be actively translated into a therapeutic option, with numerous phase I and II trials currently being conducted. Local and systemic approaches of delivery are under development.

Gene Therapy Ethics and Regulation

There are major differences in the ethical issues pertaining to somatic as opposed to germline gene therapy. In most countries, germline gene therapy, because of its potential effect on future generations, is appropriately outlawed. Our limited understanding of the complex interactions that have shaped human evolution, together with societal and cultural considerations, precludes the possibility of conceiving of responsible programs for germline genetic modifications in humans, as well as germline gene therapy approaches. However, somatic gene therapy is encouraged and performed worldwide under strict regulatory authority with remarkable congruency of guidelines in different countries and global constituencies. The concept that gene therapies constitute novel biologic drugs provides an appropriate framework for regulatory oversight.

Future Directions

In recent years, the genetic payload/transgene and delivery systems have experienced significant improvements. Rapid advances in understanding the molecular underpinnings of pathogenetic processes have facilitated translation to novel biologically based therapeutics, including gene therapy approaches. The major developments in recent years have been in the design of new types of transgenes. The discovery of RNAi (see E-Fig. 43-1) and the biogenesis and potential role of siRNA, including their apparent efficiency in the knockdown of gene expression, suggests that these developments will revolutionize gene therapy in the coming years. Viral infections still pose a major threat to humanity. Because viruses are developing resistance to the current available therapies, there is an ongoing battle between the viruses and our ability to develop novel strategies to fight them. In vitro and in vivo experiments demonstrate the effectiveness of RNAi in inhibiting many viruses that cause severe health and economic problems, including respiratory syncytial, hepatitis C, and influenza viruses.

The tragic occurrence of tumors in patients after retroviral vector-based treatment of X-SCID has motivated researchers to direct the integration of transgenes to specific human genomic sites. It is hoped that assessment of these transgene insertion navigation tools will reduce the random occurrence of insertional mutagenic events. In addition to the development of novel transgenes, there is progress with viral and nonviral vectors. The AAV vector has experienced significant improvement as a delivery system in recent years because of its capacity for targeting with different capsid serotypes and more efficient production, and this has resulted in high-level AAV transgene expression early after transduction. The lentivectors are safer now than in earlier generations and will be the subject of newly planned clinical trials.

44 THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

JÖRG J. GORONZY AND CORNELIA M. WEYAND

GENERAL PRINCIPLES OF THE IMMUNE SYSTEM

The immune system has evolved as a complex network of molecules, cells, and organs to defend against pathogenic microorganisms and noninfectious foreign substances. Beyond its role in host protection, it regulates tissue homeostasis and tissue repair. Cells of the immune system identify and remove injured, dead, and malignant cells. Immune system cells derive from hematopoietic stem cells in the bone marrow, circulate in the blood and lymph, form complex microstructures in specialized lymphoid organs, and infiltrate virtually every tissue. These cells express characteristic profiles of surface molecules, also referred to as *cluster of differentiation* (CD) molecules, with which they sense soluble or cell-bound ligands in their microenvironment. Molecular structure, ligands, and main functions of more than 300 molecules have been defined; a selected list is given in E-Table 44-1. The anatomic organization of immune system cells in lymphoid organs and their ability to circulate throughout the body and to migrate between blood and lymphoid tissues are crucial components of host defense. On activation, these cells transcribe and release cytokines, small soluble proteins that communicate between cells within the immune system or between immune system cells and cells in other tissues (Table 44-1).

Innate and Adaptive Immunity

Principally, host protection is accomplished by two types of immunity: innate and adaptive. The *innate immune system* is present in all vertebrates and is widely conserved among species. It provides the first line of defense and functions through immediate responses that use preformed proteins and preexisting cells. *Innate immunity,* broadly defined, includes physical barriers, such as epithelial layers, and chemical impediments, such as antimicrobial substances at these surfaces. Using a narrower definition, the innate immune system mediates nonspecific protection through a diverse set of cells, including monocytes, macrophages, dendritic cells, natural killer (NK) cells, eosinophils, basophils, neutrophils, and mast cells. A variety of chemical mediators, such as members of the complement system, acute phase reactants, and cytokines, contribute to inflammatory responses that develop to prevent tissue invasion by pathogens. The need for immediacy is irreconcilable with selectivity and adaptivity. Response patterns of the innate immune system are broad, and collateral tissue damage is often unavoidable. Despite the lack of specificity, innate immunity is highly effective; microbial invasion is frequently controlled, and pathogens are often eliminated. The pathogenicity of microorganisms is largely related to their ability to resist and overcome the first line of defense mounted by the innate immune system.

If invading microorganisms succeed in escaping the host's nonspecific defense mechanisms, a second line of defense, *adaptive immunity,* secures host survival. Adaptive immune responses depend on innate immunity for supplementation and augmentation and to provide crucial information about the nature of the attacker. The term *adaptive* relates to the ability of the system to adapt to the microbial challenge; it is also called *acquired* or *specific immunity*. The adaptive immune system has unique attributes, such as specificity, diversity, memory, specialization, tolerance, and homeostasis.

Immune specificity relies on two major cell types: B lymphocytes and T lymphocytes. These cells possess receptors that specifically recognize antigenic determinants and that distinguish subtle differences. To contend with the gamut of possible antigens, the adaptive immune system requires an enormous spectrum of specific receptors. An extremely high degree of discriminatory specificity is achieved by clonal distribution of the recognition structures; each individual T cell and B cell expresses a unique receptor.

The diversity of the adaptive immune system is not inherited; it is acquired somatically and is called the *lymphocyte repertoire*. The frequency of T or B cells in the naïve repertoire specific for a particular antigenic determinant is less than 1 in 10^5 and is therefore extremely low. On recognition of an antigen, the adaptive immune system reacts with clonal expansion of these infrequent antigen-responsive cells to build up a line of defense. Proliferating antigen-specific cells acquire new properties, including effector functions and the ability to function as memory cells. Specificity and memory are prerequisites for heightened reactivity to recurrent or persistent infections and also provide the basis for vaccination. Another example of the adaptive power of the specific immune system lies in specialized responses to different classes of microbes (e.g., parasites vs. viral infections). Specialization is a consequence of differentiation during the evolution of the immune response; it results in selection of the most appropriate effector pathway for a particular microbial challenge.

Molding the responding lymphocyte population to the antigenic profile of the invading pathogen inevitably involves the risk of generating cells that respond to self-antigens. To prevent injury to the host, the adaptive immune system discriminates between self and nonself. Nonreactivity to self is actively acquired and is maintained by several mechanisms, collectively called *self-tolerance*. Distinguishing self and nonself is individualized for each host and requires the selection of an individual set of nonself-reactive receptors. Consequently, the outcome of self/nonself discrimination is not transferred from generation to generation and is devoid of evolutionary pressure. In contrast, innate immunity relies on genetically programmed recognition structures and receptors that have been evolutionarily selected to recognize pathogens but not self.

Together with the capability of generating tremendous diversity and specificity, the adaptive immune system has a built-in ability to self-limit responses and to regain homeostasis. This mechanism is crucial in preventing excessive immune responses and in providing space for emerging lymphocytes that are required for a new specific immune response.

Leukocyte Migration and Homing

Mobility of the cellular constituents is fundamental to innate and adaptive immunity. To home to the site of tissue injury or to enter lymphoid organs, cells use a multistep process of adherence and activation. Initially, leukocytes roll on activated endothelial cells, activate chemokine receptors, increase adhesiveness, and eventually migrate through the endothelial layer across a chemokine gradient. The selectin family of proteins mediates the first steps of leukocyte migration. Selectins have a lectin domain and bind to carbohydrate ligands. L-selectin is present on virtually all leukocytes; P-selectin and E-selectin are expressed on activated endothelial cells, and P-selectin is also stored in platelets. Selectins capture floating leukocytes and initiate their attachment and rolling on activated endothelial cells. To transform attachment and rolling into firm adhesion, the concerted action of chemokines, chemokine receptors, and integrins is necessary. Integrins are heterodimers formed of many different α chains and β chains; different α/β combinations are expressed on different cell subsets. Only after activation can integrins interact with ligands on endothelial cells. Activation involves modification of the cytoplasmic domain of the β chain, which leads to a structural change of the extracellular domains. This process is termed *inside-out signaling*. The last step of homing is transendothelial migration. Here, the firmly attached leukocytes migrate through the endothelial cell monolayer and the basement membrane.

INNATE IMMUNE SYSTEM

Principles of Innate Immune System Activation

Activation by Pattern Recognition Receptors

The strategy of the innate immune system is to focus on the recognition of a few highly conserved structures that are preserved in large groups of microorganisms shared by entire classes of pathogens and essential for their survival and pathogenicity. The system uses a few hundred receptor structures to identify microbial invaders. This set of receptors is insufficient to cover the entire spectrum of antigens expressed on infectious agents. Structures recognized by pattern recognition receptors (PRRs) are collectively referred to as *pathogen-associated molecular patterns* (PAMPs). Examples of PAMPs are bacterial lipopolysaccharides, peptidoglycans, mannans, bacterial DNA, double-stranded RNA, and glucans.

PAMP-binding receptor families share structural characteristics, such as leucine-rich repeated domains, calcium-dependent lectin domains, and scavenger-receptor protein domains. They can be secreted to act as opsonins; the best-characterized receptor of this class is the mannose-binding lectin that binds to microbial carbohydrates and activates the lectin pathway of complement activation. Another functional class of PRRs is expressed on the

TABLE 44-1 CYTOKINES AND CYTOKINE FUNCTION

CYTOKINES	MAJOR PRODUCER CELLS	PRINCIPAL ACTION
HEMATOPOIETIN FAMILY		
IL-2	T cells	Proliferation of T cells, B cells, and NK cells
IL-3	T cells	Early hematopoiesis
IL-4	T cells, mast cells	B-cell activation, IgE switch, inhibition of T_H1 cells
IL-5	T cells, mast cells	Eosinophil growth and differentiation
IL-6	Macrophages, endothelial cells	T-cell and B-cell growth and differentiation, induction of acute phase proteins
IL-7	Bone marrow, thymic epithelium	Growth of pre-B cells and pre-T cells
IL-9	T cells	Stimulation of mast cells and T_H2 cells
IL-11	Stromal fibroblasts	Hematopoiesis
IL-13	T cells	B-cell growth and differentiation, inhibition of T_H1 cells and macrophages
G-CSF	Fibroblasts and monocytes	Neutrophil development and differentiation
IL-15	Non-T cells	Growth of T cells and NK cells
GM-CSF	Macrophages, T cells	Growth and differentiation of myelomonocytic lineage cells
INTERFERON FAMILY		
IFN-α	Leukocytes	Antiviral; increases MHC class I expression
IFN-β	Fibroblasts	Antiviral; increases MHC class I expression
IFN-γ	T cells, NK cells	Macrophage activation; increases expression of MHC molecules, Ig class switching, inhibition of T_H2 cells
TNF FAMILY		
TNF-α	Macrophages, NK cells, T cells	Induction of pro-inflammatory cytokines, endothelial cell activation, apoptosis
TNF-β (LT-α)	T cells, B cells	Cell death, endothelial activation, lymphoid organ development
LT-β	T cells, B cells	Cell death, lymphoid organ development
OTHERS		
TGF-β	Monocytes, T cells	Anti-inflammatory; inhibits cell growth, induces IgA secretion
IL-1α, IL-1β	Macrophages, endothelial cells	Acute phase response, fever, macrophage activation, costimulation
IL-10	T cells, macrophages	Suppression of macrophage functions
IL-12	Macrophages, dendritic cells	NK cell activation, T_H1 cell differentiation
IL-16	T cells, mast cells, eosinophils	Chemoattractant for CD4 T cells, monocytes, and eosinophils
IL-17	CD4 memory cells	Cytokine production by epithelia, endothelia, and fibroblasts
IL-18	Macrophages	IFN-γ production by T cells and NK cells
IL-23	Macrophages, dendritic cells	T_H17 cell differentiation

CD = cluster of differentiation; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; IFN = interferon; Ig = immunoglobulin; IL = interleukin; LT = lymphotoxin; MHC = major histocompatibility complex; NK = natural killer; TGF = transforming growth factor; T_H = helper T lymphocyte; TNF = tumor necrosis factor.

surface of phagocytes and facilitates endocytosis. The macrophage mannose receptor and the macrophage scavenger receptor are the best-known examples. These receptors are essential for the clearance of microbes from the circulation. A third class of PRRs controls cell activation (Fig. 44-1); the most important members are toll-like receptors (TLRs). TLRs are expressed on either the cell membrane or the endosome to sense extra- or intracellular pathogens. They function by regulating the activity of nuclear factor-κB (NF-κB) and interferon signaling pathways and control the expression of many inflammatory cytokines and cell surface molecules. Prominent members of the TLR family are TLR4, which, in conjunction with other cell surface molecules, binds bacterial lipopolysaccharides; TLR2, which recognizes bacterial peptidoglycans and lipoproteins; and TLR9, which binds to bacterial DNA motifs.

PRRs used by the innate immune system are fundamentally different from the antigen-specific receptors generated in the adaptive immune system. The receptors of the innate immune system are encoded in the germline and are under evolutionary pressure. They are shared by many different cells, including macrophages and dendritic cells, and are not clonally distributed (i.e., different cell types display identical specificity). Finally, PRRs do not recognize self, so they do not carry the risk for autoimmune injury, although exceptions to this rule (e.g., recognition of heat shock proteins) have been described.

Regulation by Major Histocompatibility Complex Class I–Recognizing Receptors

Several cells of the innate immune system require reversal of inhibition to enter the activation cycle. Loss of inhibitory signals in constitutively activated cells is particularly important for NK cells. NK cells are poised to attack, but they are held in check by inhibitory receptors that recognize major histocompatibility complex (MHC) class I or MHC class I–like molecules. The observation that NK cells kill target cells lacking MHC class I molecules led to the *missing-self hypothesis*. The principle that immune cells are kept in check by recognizing self-determinants is appreciated now as fundamental in the immune system.

Provision of negative signals is closely linked to the recognition of MHC class I molecules. Currently, three types of MHC class I–recognizing receptors are known. C-type lectin receptors (CD159) recognizing human leukocyte antigen E (HLA-E) and killer immunoglobulin-like receptors (CD158) specific for HLA-C and, to a lesser extent, HLA-A and HLA-B are expressed predominantly on NK cells. Immunoglobulin-like transcript receptors (CD85) are more widely expressed. Immunoglobulin-like transcript receptor 2 is expressed on NK cells, B cells, monocytes, dendritic cells, and macrophages. Immunoglobulin-like transcript receptors 3 and 4 are encountered on monocytes, dendritic cells, and macrophages. By screening cell surfaces for the expression of MHC class I molecules, the innate immune system collects information about the intactness of tissues, emphasizing the crucial role of MHC class I molecules as markers of tissue integrity. Recognition of MHC class I molecules provides a negative signal that suppresses cell activity. However, all receptor families also include stimulatory isoforms that mediate an activating signal. The balance between these opposing signals is finely tuned, ultimately determining whether innate immunity is initiated.

Activation by Fc Receptors

Most cells of the innate immune system possess immunoglobulin crystallizable fragment (Fc) receptors (FcRs) and can bind antibodies attached to antigens (see Fig. 44-1). FcRs specifically interact with the constant region (Fc portion) of immunoglobulins. Each member of the FcR family displays specificity for one or a few immunoglobulin isotypes. The isotype of the antibody determines which cell type is activated in a given response. Triggering of most FcRs transmits activating signals; however, inhibitory FcRs do exist. Phagocytic cells, such as neutrophils and macrophages, are equipped with FcγRs that are activated by immunoglobulin G (IgG) antibodies,

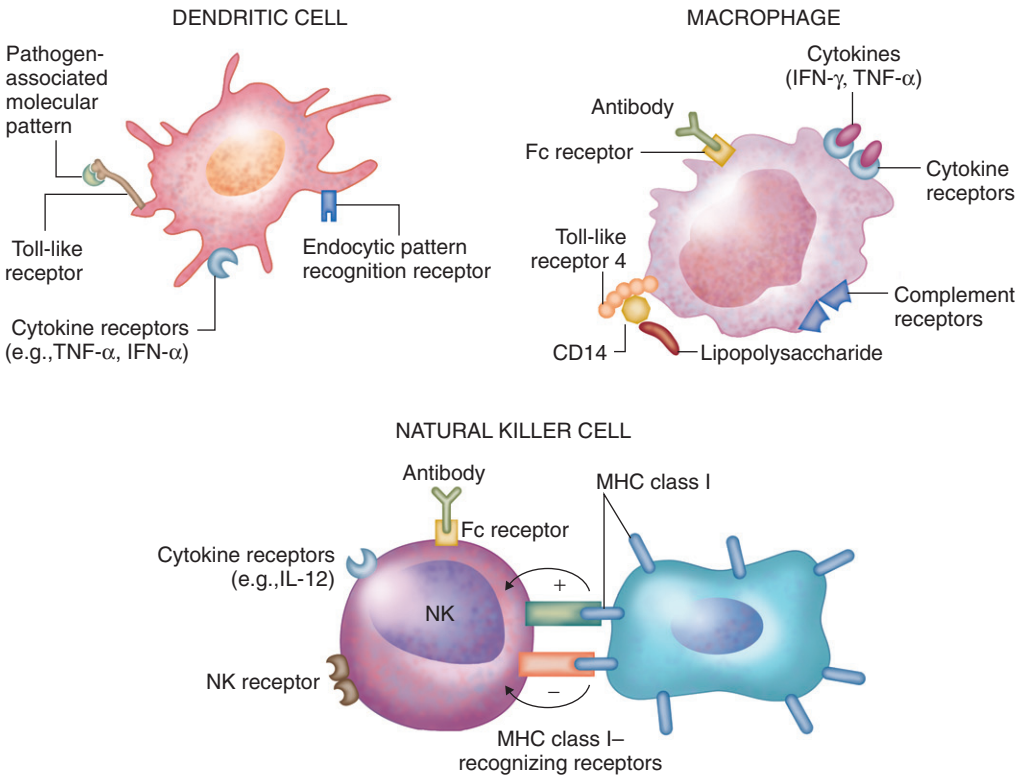

FIGURE 44-1. Activation pathways in the innate immune system. Cells of the innate immune system recognize microorganisms and tissue damage caused by either infection or malignancy. Dendritic cells and monocytes/macrophages use a multitude of receptors to sense constituents of pathogens—often bacterial molecules common to many classes of microorganisms—and respond to cytokines and endogenous stimulators released from injured cells. Binding of complement factors can also trigger cell activation. Self-recognition of major histocompatibility complex (MHC) class I molecules by natural killer (NK) cells can deliver positive or negative signals. Lack of MHC class I molecules on the target cell surface activates NK cells to kill the target. IFN = interferon; IL = interleukin; TNF = tumor necrosis factor.

particularly IgG1. Ligation of an FcγR triggers phagocytosis of the antigen, activation of respiratory burst, and induction of cytotoxicity. On NK cells, FcγRs initiate antibody-dependent cell-mediated cytotoxicity. In this process, the cytolytic machinery of NK cells is triggered by the binding of IgG1-coated or IgG3-coated target cells. FcRs on mast cells, basophils, and activated eosinophils are specific for IgE. In contrast to other FcRs, they bind monomeric antibody molecules with extremely high affinity. Cross-linking of the constitutively cell surface–bound IgE induces cell activation and the release of cytoplasmic granules.

Activation by Cytokines

Generally, cells of the innate immune system are exquisitely sensitive to the action of cytokines. Cytokines are soluble, low-molecular-weight glycoproteins that derive from many tissue sources. They are chemical messengers that convey information between cells, regulate the differentiation of effector cells, and modulate immune responses. Important examples of cytokine-mediated signals in the innate immune system are interferon-γ (IFN-γ), produced by NK cells, which is the most potent activator of macrophages; interleukin-6 (IL-6), which induces acute phase reactants; IL-12, IL-23, and IL-27, derived from macrophages and dendritic cells, which coordinate the development of adaptive immune responses; IL-15, which regulates the activity and proliferation of NK cells; and type I IFN secreted at the time of injury, which activates NK cells and dendritic cells (see Fig. 44-1).

Cellular Elements of the Innate Immune System

Monocytes and Macrophages

Monocytes circulate in the peripheral blood with a half-life of 1 to 3 days. Macrophages arise from monocytes that have migrated out of the circulation and have proliferated and differentiated in tissue. Tissue macrophages are common in lymphoid organs, but they are also present in connective tissues, such as the perivascular space, and in the lining of serous cavities (pleura and peritoneum). Specialized macrophages include alveolar macrophages in the lung, Kupffer cells in the liver, osteoblasts in bone, microglia in the central nervous system, and type A synoviocytes in the synovial membrane. Macrophages are activated through the triggering of PRRs or FcRs, and they respond vigorously to IFN-γ (see Fig. 44-1). They secrete myriad products, including hydrolytic enzymes, reactive oxygen species, cytokines (tumor necrosis factor-α [TNF-α], IL-1, IL-6, IL-10, IL-12, IL-15, and IL-18), and chemokines. They phagocytose and expose the engulfed microorganism to a wide range of toxic intracellular molecules, including reactive oxygen species, nitric oxide, antimicrobial cationic proteins and peptides, and lysosomal enzymes. In addition to attacking microbial organisms, macrophages remove dying and dead host cells. They recognize molecules expressed on apoptotic cells and eliminate them without initiating an inflammatory response. Finally, they play a crucial role in the recruitment of adaptive immune responses. After capturing antigen, they function as antigen-presenting cells for T lymphocytes. In this function, however, they are less important than dendritic cells.

Dendritic Cells/Langerhans Cells

Dendritic cells represent the major cell type linking the innate and adaptive immune systems. Their primary function is the presentation of antigens to T cells. They are the only cell type that can activate naïve T cells and initiate adaptive immune responses. Two major lineages of dendritic cells exist: myeloid and plasmacytoid dendritic cells. When positioned in the skin, myeloid dendritic cells are referred to as *Langerhans cells*. They constantly endocytose and digest extracellular molecules but usually do not display these molecules at a sufficient density to activate T cells. On receiving a stimulatory signal, they convert into highly efficient antigen-presenting cells. Activation signals can derive from PAMPs or from host cells that react to injury and secrete mediators such as TNF-α or heat shock proteins (see Fig. 44-1). Activation causes dendritic cells to change their expression profile of chemokine receptors and to migrate from the local tissue to lymph nodes. In parallel, they begin expressing accessory molecules on their cell surface, a prerequisite for T-cell activation, and to secrete cytokines (e.g., IFN-α by plasmacytoid dendritic cells, or IL-12 and IL-23 by myeloid dendritic cells) that orchestrate T-cell differentiation. When they arrive in the T-cell zone of the lymph node, they display MHC–peptide complexes with peptides derived from endocytosed and digested antigens. With high surface expression of MHC and accessory molecules, dendritic cells optimize the process of antigen presentation and T-cell priming (Fig. 44-2).

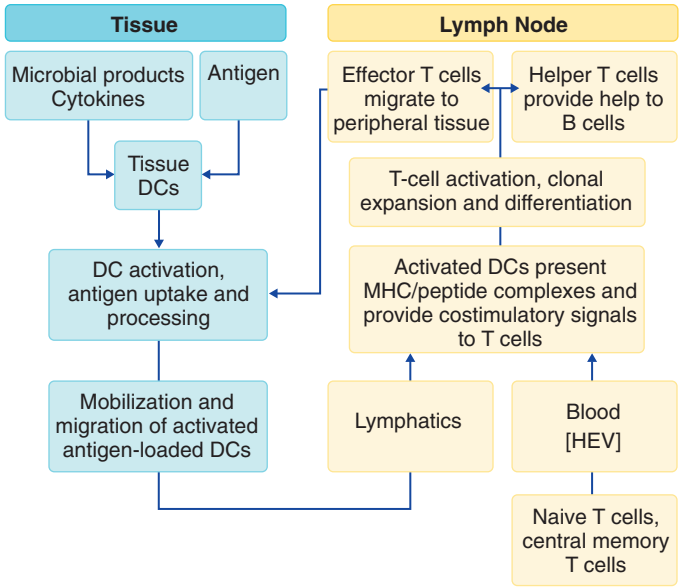

FIGURE 44-2. Interface between the innate and adaptive immune systems. Dendritic cells (DCs) reside in the tissue, where they recognize and ingest antigens. If they also receive an activating signal (e.g., by binding pathogen-associated molecular patterns or cytokines), they enter lymph vessels and travel to regional lymph nodes. In parallel, they mature into efficient antigen-presenting cells that express high levels of cell surface major histocompatibility complex (MHC) and costimulatory molecules. In the T-cell zones, DCs present the antigen engulfed in the peripheral tissue to prime naïve T cells. By capturing and transporting antigens and priming naïve T cells, DCs integrate responses of the innate and adaptive immune systems. HEV = high endothelial venules.

Natural Killer Cells

NK cells provide the first line of defense against viral infections and other intracellular pathogens while adaptive responses are generated. NK cells are sensitized by cytokines released from macrophages and dendritic cells. They function by secreting cytokines, mainly IFN-γ, which activate macrophages and other cells. They also are poised to kill virus-infected cells. NK cells induce apoptosis of the target cells by injecting pore-forming enzymes and granzymes. One of the interesting features of NK biology is the activation of these lymphocytes when MHC class I molecules on target cells are lost (see Fig. 44-1). NK cells are important in tumor surveillance because they are able to kill MHC class I–deficient tumor cells that are no longer susceptible to adaptive immune responses.

Neutrophils, Eosinophils, and Basophils

Neutrophils

Neutrophils are the most abundant circulating white blood cells. They are recruited rapidly to inflammatory sites and are capable of phagocytosing and digesting microbes. Activation of neutrophils and phagocytosis is facilitated through the triggering of FcRs or complement receptors. During phagocytosis, the pathogen is first surrounded by the phagocyte membrane, and then internalized in membrane-bound vesicles known as *phagosomes*. Phagosomes fuse with lysosomes, which contain enzymes, proteins, and peptides that inactivate and digest microbes. Beyond their phagocytic capability, neutrophils produce a variety of toxic products. The release of toxic products is known as the *respiratory burst* because it is accompanied by an increase in oxygen consumption. During the respiratory burst, oxygen radicals are generated by lysosomal reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidases. Neutrophils are short-lived cells, dying soon after they have been activated. Secretion of their granule products, in particular enzymes (myeloperoxidase, elastase, collagenase, and lysozyme), causes direct cellular injury and damages macromolecules at inflamed sites.

Eosinophils

In contrast to macrophages and neutrophils, eosinophils (Chapter 173) are only weakly phagocytic. They are potent cytotoxic effector cells against parasites. Their major effector mechanism is the secretion of various cationic proteins (major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin). These proteins are released into the extracellular space, where they directly destroy the invading microorganism, but they can also damage host tissue.

Basophils

Basophils and tissue mast cells are important reservoirs of inflammatory mediators such as histamines, prostaglandins, leukotrienes, and selected cytokines. Basophils and tissue mast cells have high-affinity receptors for monomeric IgE. They play a role in atopic allergies, in which allergens bind immunoglobulin (IgE) and cross-link FcεRs. Their function in normal immune responses is incompletely understood.

Soluble Factors in Innate Defenses

Effector functions of the cells of the innate immune system are enhanced by many circulating proteins. A particularly important contribution derives from the complement system, a group of plasma enzymes and regulatory proteins that are converted from inactive pro-enzymes to active enzymes in a controlled and systematic cascade, which is crucial in linking microbial recognition to cellular effector function (Chapter 47). Mannose-binding lectin circulates in the plasma, functioning as an opsonin, and is involved in activation of the complement pathway. C-reactive protein, an acute phase protein, participates in opsonization by binding to bacterial phospholipids. Finally, the innate immune system could not work without the cytokines that regulate the recruitment and activation of leukocytes (see Table 44-1). Cells of the innate immune system are not only the principal producers of such cytokines but also their targets.

ADAPTIVE IMMUNE SYSTEM

Principles of Adaptive Immune System Activation: Recognition of Antigen

Structure of Antigen-Specific Receptors

The innate immune system recognizes structural patterns that are common in the microbial world, whereas the adaptive immune system is designed to respond to the entire continuum of antigens. This goal is achieved through two principal types of antigen recognition receptors: antibodies and T-cell receptors (TCRs). Antibodies are expressed as cell surface receptors on B cells or are secreted. They recognize conformational structures formed by the tertiary configuration of proteins. In contrast, α/β TCRs fit specifically to epitopes formed by a small linear peptide embedded into MHC molecules on the surface of antigen-presenting cells.

Antibodies consist of two identical heavy chains and two identical light chains, which are covalently linked by disulfide bonds. The amino (N)-terminal domain of each chain is variable and represents the recognition structure that interacts with the antigen. Each antibody has two binding arms of identical specificity. The carboxy (C)-terminal ends of the heavy and light chains form the constant region, which defines the subclass of the antibody (κ or λ for light chains; IgM, IgA, IgD, IgE, or IgG for heavy chains). Additional subclasses can be distinguished for IgG and IgA. The constant region of antibodies includes the Fc region. Fc regions can polymerize (IgA) or pentamerize in the presence of a J (joining) chain (IgM). Fc regions are also the ligand for the FcRs on cells of the innate immune system.

TCRs are dimers of α chains and β chains or of γ chains and δ chains, each of which contains three complementary-determining binding sites in the N-terminal domain. These complementary-determining sites define the specificity. α/β TCRs exclusively recognize peptide fragments in the context of MHC molecules. γ/δ TCRs are more variable and can recognize certain glycolipid antigens in the context of MHC-like molecules or even unprocessed antigens, functioning similar to antibodies. The repertoires of antibodies and TCRs are extremely diverse and have been estimated in the human to account for 10^8 to 10^9 unique (of 10^{15} possible) combinations. This enormous diversity cannot be genetically encoded; it must be acquired. Its foundation consists of fewer than 400 genes that are recombined and modified. Immunoglobulin heavy chains are formed from four gene segments encoded on chromosome 14—the variable, diversity, joining, and constant region gene segments. Also, TCR β chains and δ chains are assembled by the recombination of variable, diversity, joining, and constant region segments of TCR genes. Immunoglobulin light chains and TCR α chains and γ chains lack the diversity segment and are composed of three gene segments. During antibody or TCR rearrangement, gene segments are cut out by nucleases and spliced together at the DNA level to form linear coding units for each receptor gene. Through the combination of several different mechanisms, an enormous diversity of receptors is generated. First, the genome contains multiple forms of gene segments; each receptor or antibody uses a different

combination of these gene segments. Second, the splicing process is imprecise, introducing nucleotide variations at the variable-diversity, diversity-joining, and variable-joining junctions. These inaccuracies lead to frame shifts and result in completely different amino acid sequences. Finally, random nucleotides can be inserted at the junctional region by an enzyme, deoxyribonucleotidyl transferase.

Once generated, TCR sequences remain unchanged. This rule does not apply to immunoglobulins, which can undergo editing. Immunoglobulin editing includes replacement of an entire variable region (receptor editing); class switching during immune responses, in which the variable-diversity-joining unit combines with different constant region genes (isotype switching); or somatic hypermutation, in which the antigen contact areas of the antibody undergo mutations during an immune response to improve the affinity (affinity maturation).

Antigen Processing

T cells do not recognize native antigens but rather peptide fragments that are displayed in the context of MHC class I and class II molecules. The two classes of MHC molecules are used as restriction elements by two different subsets of T cells. $CD4^+$ T cells recognize antigen peptides embedded into MHC class II molecules, whereas $CD8^+$ T cells are directed against peptides complexed with MHC class I molecules. Generally, MHC class II molecules are expressed only on specialized antigen-presenting cells, such as dendritic cells, monocytes, macrophages, and B cells. Peptides bound to MHC class II molecules derive from extracellular antigens that are captured and internalized into endosomes to be digested by proteinases, notably cathepsin. Occasionally, intracellular proteins or membrane proteins are also funneled into this pathway. MHC class II molecules are assembled in the endoplasmic reticulum in association with a protein called the *invariant chain* (Fig. 44-3).

The molecules are transported to the endosome, where the invariant chain is removed from the peptide-binding cleft, making the cleft accessible to peptides derived from extracellular proteins. MHC class II molecules, stabilized by peptides of 10 to 30 amino acids, are displayed on the cell surface, where they can be recognized by $CD4^+$ T cells.

MHC class I–associated peptides are produced in the cytosol by the proteosome, a large cytoplasmic multiprotein enzyme complex (see Fig. 44-3). Specialized transporter proteins, called *transporter in antigen processing* (TAP), facilitate translocation from the cytosol to the endoplasmic reticulum. There, the peptides bind to newly formed MHC class I molecules and are transported to the cell surface, where they are recognized by antigen-specific $CD8^+$ T cells.

The nature of the antigen-processing pathway determines the sequence of events in immune responses. Extracellular antigens, in general, enter the endosomal pool and associate with MHC class II molecules to stimulate $CD4^+$ T cells. Cytosolic antigens, including antigens from intracellular infectious agents, are degraded and displayed in the context of MHC class I molecules to initiate $CD8^+$ T-cell responses.

Cellular Elements of the Adaptive Immune System

T Cells

T-Cell Development

T precursor cells are derived from hematopoietic stem cells seeded into the thymus, where all the subsequent stages of T-cell maturation occur (Fig. 44-4). Pre-T cells express two enzymes, recombinase and terminal

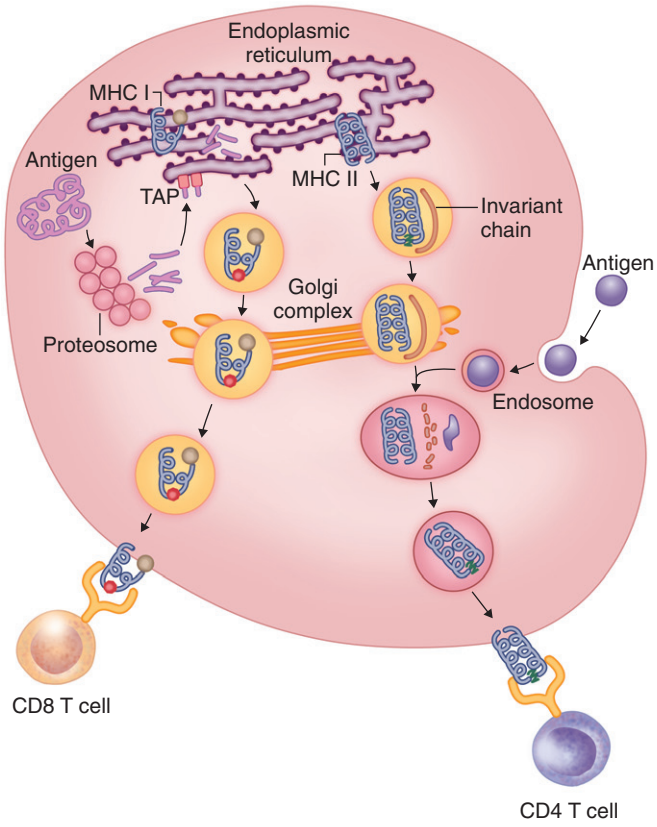

FIGURE 44-3. Pathways of antigen processing and delivery to major histocompatibility complex (MHC) molecules. Cytosolic proteins are broken down by the proteosome to generate peptide fragments, which are transported into the endoplasmic reticulum by specialized peptide transporters (TAP). After peptides are bound to MHC class I molecules, MHC-peptide complexes are released from the endoplasmic reticulum and travel to the cell surface, where they are ligands for $CD8^+$ T-cell receptors (TCRs). Extracellular foreign antigens are taken into intracellular vesicles, called *endosomes*. As the pH in the endosomes gradually decreases, proteases are activated that digest antigens into peptide fragments. After fusing with vesicles that contain MHC class II molecules, antigenic peptides are placed in the antigen-binding groove. Loaded MHC class II–peptide complexes are transported to the cell surface, where they are recognized by the TCRs of $CD4^+$ T cells.

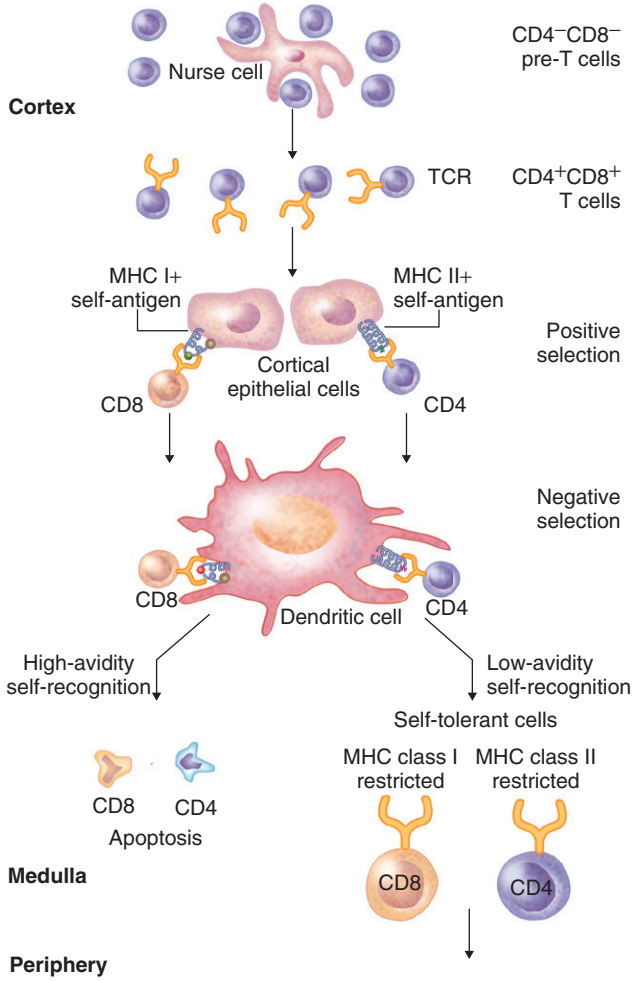

FIGURE 44-4. Maturation of T cells in the thymus. Precursors committed to the T-cell lineage arrive in the thymus and begin to rearrange their T-cell receptor (TCR) genes. Immature T cells with receptors binding to self–major histocompatibility complex (MHC) on cortical epithelial cells receive signals for survival (positive selection). At the corticomedullary junction, surviving T cells probe self-antigens presented by dendritic cells and macrophages. T cells reacting strongly to self-antigens are deleted by apoptosis (negative selection). T cells released into the periphery are tolerant toward self and recognize foreign antigens in the context of self-MHC.

deoxynucleotidyl transferase, enabling them to recombine TCR genes. The β chain of the TCR is rearranged first and is expressed together with a pre-TCR α chain. Signals from the immature TCR complex inhibit rearrangement of the second β-chain allele and induce T-cell proliferation and expression of the CD4 and CD8 molecules. Subsequently, the TCR α chain is recombined. From here, the T cell undergoes many differentiation and selection steps modulated by the thymic microenvironment. Early stages of thymocytes reside in the thymic cortex, where they mostly interact with epithelial cells. They then migrate toward the medulla, encountering dendritic cells and macrophages at the corticomedullary junction. Thymic stromal cells regulate T-cell proliferation by secreting lymphopoietic growth factors, such as IL-7. Interactions of the TCR with MHC molecules expressed on epithelial cells and on dendritic cells or macrophages determine the fate of the thymocyte. Low-avidity recognition of peptide-MHC complexes on thymic epithelial cells by the TCR results in positive selection. This recognition event rescues cells from apoptotic cell death and ensures that only T cells with functional receptors survive. Thymocytes that express a receptor not fitting any MHC antigen complex die by neglect. High-affinity interaction between the TCR and peptide-MHC complex induces apoptotic death of the recognizing T cell. This process of negative selection eliminates T cells with specificity for self-antigens and is responsible for central tolerance to many autoantigens. It has been estimated that approximately 1% of thymocytes survive the stringent selection process. While undergoing selection, T cells continue to differentiate, with orderly expression of cell surface molecules. Thymocytes expressing CD4 and CD8 molecules develop into single-positive $CD4^+$ helper T cells that have been selected on MHC class II complexes or $CD8^+$ cytotoxic T cells that are restricted to MHC class I complexes.

T-Cell Stimulation and Accessory Molecules

T-cell activation is initiated when TCR complexes recognize antigenic peptides in the context of the appropriate MHC molecule on the surface of an antigen-presenting cell. Antigen recognition by T cells results in proliferation and differentiation and triggers various effector functions. Stimulation of the TCR is not sufficient and needs to be complemented by the interaction of accessory molecules on the T cell and their ligands on the antigen-presenting cell. A spectrum of accessory molecules is known (see E-Table 44-1). The coreceptors CD4 and CD8 interact with MHC class II and class I molecules and support activation signals through the TCR. Adhesion molecules (integrins) stabilize the interactions between T cells and antigen-presenting cells. Finally, specialized costimulatory molecules provide a second signal in addition to the TCR signal. In the absence of such a second signal, T cells undergo apoptosis or are rendered nonresponsive and anergic.

The best-known and best-studied costimulatory molecule expressed on T cells is the CD28 molecule, which binds to the CD80/CD86 ligands expressed on activated antigen-presenting cells. CD28-mediated signals are mandatory for the expression of many activation markers on the responding T cells and, in particular, for the secretion of IL-2.

Signals from the TCR result in the activation of many genes and entry of the T cell into the cell cycle. The signals are transmitted by a cascade of cytoplasmic events. Cross-linking of the TCR and associated CD3 molecules results in the recruitment and activation of phosphotyrosine kinases and the phosphorylation of molecular constituents of the TCR and various adapter molecules; signals mediated through the TCR activate several biochemical pathways, which collectively lead to the activation of transcription factors that regulate gene expression.

Three major variables determine the outcome of TCR stimulation: the duration and affinity of the TCR-antigen interaction, the maturation stage of the responding T cell, and the nature of the antigen-presenting cell. Antigen-presenting cells are gatekeepers in the initiation of T-cell responses. They can upregulate the expression of accessory molecules that provide costimulatory signals. MHC-peptide complexes are particularly dense on dendritic cells, enabling them to activate naïve T cells. In contrast, memory and effector cells have a lower threshold for activation and can react to antigens presented on peripheral tissue cells.

T-Cell Differentiation and Effector Functions

T-cell activation induces T-cell proliferation, with the goal of clonally selecting and expanding antigen-specific T cells. The extent of clonal proliferation is impressive. Antigen-specific $CD8^+$ T cells expand by a factor of 50,000; $CD4^+$ T cells expand slightly less. During the phase of rapid growth, T cells differentiate from naïve T cells that are essentially devoid of effector functions into effector T cells. The transition into effector cells is associated with a fundamental shift in functional profiles. First, effector T cells have a lower activation threshold; they do not require costimulation and can scan tissues that lack professional antigen-presenting cells. Second, they switch the expression of chemokine receptors and adhesion molecules to gain access to peripheral tissues. Finally, they gain effector functions. The principal effector function of $CD8^+$ T cells is to lyse antigen-bearing target cells. $CD4^+$ T cells produce many cytokines and express cell surface molecules that are important in the activation of phagocytes and other lymphocytes. $CD8^+$ T cells are committed to differentiating into cytotoxic T cells as they emerge from the thymus; the spectrum of options for $CD4^+$ T cells is larger. Different subsets of $CD4^+$ effector T cells can be distinguished based on the preferential production of certain cytokines (see Table 44-1). T_H1 T cells produce predominantly IFN-γ and TNF-α and are involved in cell-mediated immunity, such as delayed-type hypersensitivity reactions. T_H2 T cells preferentially produce IL-4, IL-5, and IL-13, cytokines that regulate B-cell responses and the activation of eosinophils. T_H17 T cells producing IL-17 and IL-22 induce an intense inflammatory response to eliminate difficult to clear pathogens. Follicular T helper cells home to lymphoid follicles, where they express CD40 ligand (CD154) and secrete IL-21 and other cytokines to provide B-cell help. The decision as to which differentiation pathway to take is made during the early stages of T-cell activation and depends on many factors, including the cytokines produced by cells of the innate immune system in the microenvironment, the nature of costimulatory signals, and the avidity of the TCR–MHC antigen interaction. Lineage development is generally correlated with the expression of specific transcription factors (T-bet for T_H1 cells, GATA3 for T_H2 cells, or RORγt for T_H17 cells). Lineage commitment is not absolute and is not terminal, and transition between different effector types is possible.

Cytotoxic T-cell effector functions are also triggered by antigen recognition by the TCR. On recognizing the appropriate MHC class I–peptide complex, $CD8^+$ T cells induce apoptosis in target cells. The T cell polarizes toward the area of antigen contact; specialized lytic granules are clustered in the contact area. A pore-forming protein, perforin, is released from the lytic granules and inserted into the target cell membrane. Proteases (granzymes) are injected into the target cells to initiate the apoptotic process by activating enzyme cascades. Mechanisms deployed by $CD8^+$ T cells are essentially identical to those of NK cells. $CD4^+$ T cells can also induce apoptosis, but by a different mechanism from $CD8^+$ T cells. Upon activation, they express cell surface molecules such as Fas ligand (CD178) and TRAIL, which initiate the apoptotic cascade selectively in cells expressing the respective ligands Fas (CD95) or the death receptors DR4 and DR5.

Regulatory T Cells

Depending on their cytokine profile, $CD4^+$ T cells have the ability to cross-regulate each other, influence T-cell differentiation, and suppress T-cell effector activity. Classic examples of T cells with regulatory activity cells generated during the normal immune response are IL-10– and transforming growth factor-β (TGF-β)–producing cells. In addition, specialized subsets of regulatory T (Treg) cells are characterized by expression of the transcription factor forkhead box P3 (Foxp3). Naturally occurring $Foxp3^+$ Treg cells are generated during T-cell development in the thymus and recognize self-antigens. $Foxp3^+$ Treg cells can also arise from conventional $CD4^+$ T cells in the periphery. Phenotypically and functionally, natural and inducible Treg cells are indistinguishable; their development and function depend on Foxp3, and they are able to suppress T-cell expansion and constitutively express several cell surface markers. However, none of these markers is specific for Treg, as activated T cells can also express them. Treg cells are important in peripheral tolerance, controlling the expansion of autoreactive T cells, and they also play a role in immune responses to pathogens by virtue of their ability to suppress T-cell effector function. Despite extensive studies in various models, the mechanism by which Treg cells functions in vivo remains poorly understood.

T-Cell Homeostasis

Effective immunity depends on the ability of the immune system to generate large numbers of antigen-specific T cells rapidly, yet the space in the T-cell compartment is limited. To avoid competition for space and resources and to prevent perturbation of T-cell diversity by lifelong exposure to antigens, the adaptive immune system employs several counterbalancing mechanisms. In the later stages of the activation process, a strong negative signal derives from interaction of the T-cell molecule cytotoxic T-lymphocyte antigen (CTLA)-4 (CD152) with CD80/CD86 on antigen-presenting cells. In

addition, T cells undergo activation-induced cell death. Activated $CD4^+$ T cells begin to secrete Fas ligand and acquire sensitivity to Fas-mediated death, inducing apoptotic suicide and fratricide in neighboring T cells. These mechanisms impose constraints in the early stages of the T-cell antigen response. Other mechanisms control the rapid decline of expanded antigen-specific T cells when elimination of the antigen has been achieved. Removal of the driving antigen causes a deprivation of cytokines and costimulatory molecules, and growth factor–deprived T cells die from apoptosis. It has been estimated that only 5% of the antigen-expanded population survives after antigen clearance.

B Lymphocytes

B-Cell Development

B cells are generated in the bone marrow. Supported by a specialized microenvironment of nonlymphoid stromal cells, lymphoid stem cells differentiate into distinctive B-lineage cells. Driven by chemokines (stromal cell–derived factor 1) and cytokines (IL-7), precursor B cells enter a process of tightly controlled sequential rearrangements of heavy chain and light chain immunoglobulin genes. On pre-B cells, the membrane μ chain is associated with a surrogate light chain to form a pre-B-cell receptor (BCR). Signals provided through this receptor induce proliferation of a progeny that subsequently rearranges different light chain gene segments.

It is estimated that only 10% of B cells generated in the bone marrow reach the circulating pool. Losses are mostly due to negative selection and clonal deletion of immature B cells that express receptors directed against self-antigens. Cross-linking of surface IgM by multivalent self-antigens causes immature B cells to die. Such self-reactive B cells can be rescued from death by replacing the light chain with a newly rearranged light chain that is no longer self-reactive (receptor editing). On maturation, B cells begin to express surface IgD. B cells positive for IgD and IgM are exported from the bone marrow and seed peripheral lymphoid tissues (Fig. 44-5).

B-Cell Stimulation

Mature B cells are activated by soluble and cell-bound antigens to develop into antibody-secreting effector cells. B cells respond to a large variety of antigens, including proteins, polysaccharides, and lipids. Binding of antigen to cell surface IgM molecules induces BCR clustering. In addition to the antigen-binding immunoglobulin, the BCR comprises two proteins, Ig-α and Ig-β. The Ig-α/Ig-β heterodimer functions to transduce a signal and initiates the intracellular signaling cascade. The composition of the BCR, with a ligand-binding and a signal-transducing unit, and the signaling events that lead to gene induction are similar to those of the TCR. BCR triggering can be enhanced by coreceptors. The coreceptor complex is composed of CD81, CD19, and CD21; CD21 binds to complement fragments on opsonized antigens.

Naïve B cells require accessory signals in addition to triggering of the immunoglobulin receptor. They receive second signals either from helper T cells or from microbial components. Microbial constituents, such as bacterial polysaccharides, can induce antibody production in the absence of helper T cells (thymus-independent antigens). In the case of protein antigens (thymus-dependent antigens), the initial BCR stimulation prepares the cell for subsequent interaction with helper T cells. These activated B cells start to enter the cell cycle; upregulate cell surface molecules, such as CD80 and CD86, that provide costimulatory signals to T cells; and upregulate certain cytokine receptors. These B cells are prepared to activate helper T cells and to respond to cytokines secreted by those T cells, but they cannot differentiate into antibody-producing cells in the absence of T-cell help.

B-Cell Differentiation

Differentiation of antigen-activated B cells depends on interaction with helper T cells. B cells use their antigen receptor not only to recognize antigens but also to internalize them. After processing endocytosed antigens, MHC class II–peptide complexes appear on the cell surface, where antigen-specific $CD4^+$ T cells detect them. Also, B cells express costimulatory molecules and provide optimal conditions for T-cell activation. On activation, $CD4^+$ T cells express CD154 on their surface and are able to stimulate the CD40 molecule on their B-cell partner. CD40-CD154 interaction is essential for subsequent B-cell proliferation and differentiation. Cytokines secreted by the helper T cells act in concert with CD154 to amplify B-cell differentiation and to determine the antibody type by controlling isotype switching. Isotypes greatly influence the versatility of antibodies as effector molecules, and cytokines drive isotype switching by stimulating the transcriptional activation of heavy chain constant region genes. T-cell–dependent B-cell differentiation and maturation take place in germinal centers, specialized structures in secondary lymphoid tissues (see Fig. 44-5). There, the variable regions of B cells are altered by somatic hypermutation, leading to the production of large amounts of high-affinity antibodies. Subsequently, B cells that possess immunoglobulin receptors with high affinity for antigens in the germinal center are selected for survival (affinity maturation).

Lymphocytes and Lymphoid Tissue

The initiation of adaptive immune responses depends on rare antigen-specific T cells and B cells meeting antigen-presenting cells and their relevant antigen. The recognition of a specific antigen in the tissue by uncommon T

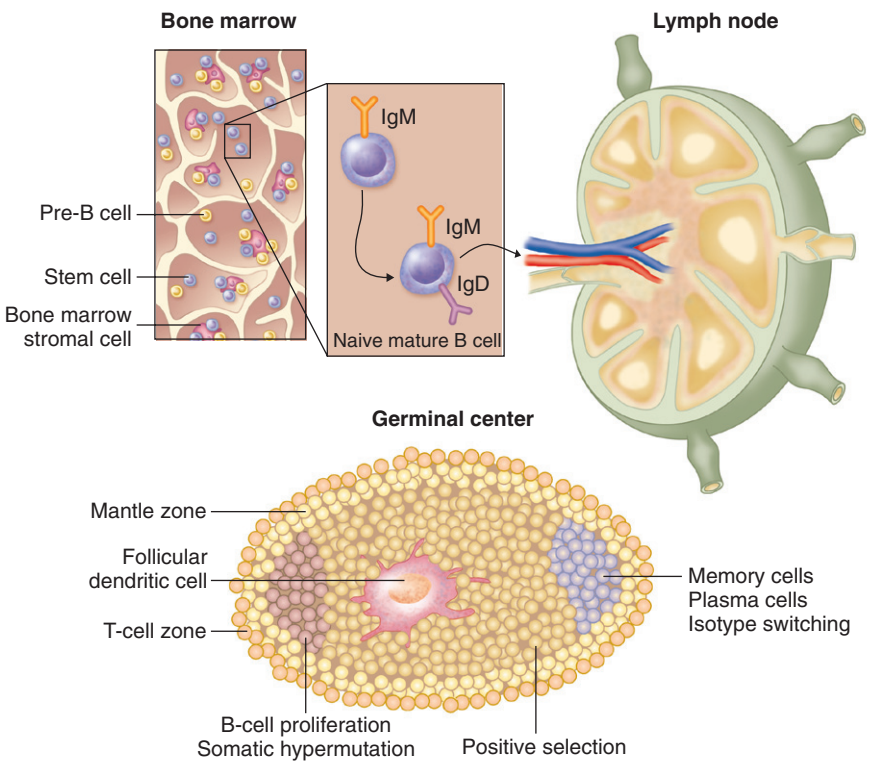

FIGURE 44-5. B-cell development and differentiation. The early stages of B-cell development occur in the bone marrow, with cells progressing through a developmental program determined by the rearrangement and expression of immunoglobulin (Ig) genes. Immature B cells with receptors for multivalent self-antigens die in the bone marrow. Surviving B cells coexpress IgD and IgM surface receptors. They are seeded into peripheral lymphoid organs, where they home to selected locations and receive signals to survive and become longer-lived naïve B cells. Antigen-binding B cells and antigen-presenting B cells that receive help from antigen-specific T cells are activated through membrane-bound and secreted molecules. Activated B cells migrate into the follicles, leading to the formation of germinal centers. B cells in germinal centers undergo somatic hypermutation of immunoglobulin genes; cells with high affinity for antigens presented on the surface of follicular dendritic cells are selected to differentiate into either memory B cells or plasma cells.

cells has a low probability, and it is unlikely that sufficient numbers of antigen-presenting cells and lymphocytes can be brought together to provide crucial momentum. The immune system uses specialized lymphoid microstructures to bring antigens to the site of lymphocyte traffic and accumulation. Secondary lymphoid organs include the spleen for blood-borne antigens, the lymph nodes for antigens encountered in peripheral tissues, and the mucosa-associated, bronchial-associated, and gut-associated lymphoid tissues, where antigens from epithelial surfaces are collected. Lymphocytes circulate through secondary lymphoid organs, constantly searching for their antigen. Their homing to secondary lymphoid organs is facilitated by specialized microvessels, called *high endothelial venules*. Secondary lymphoid tissues have developed several strategies to sequester the relevant antigen. Antigens in peripheral tissue are encountered first by dendritic cells that, after activation, are mobilized to transport antigens into the local lymph nodes by the draining lymph. These antigen-bearing dendritic cells enter the lymph nodes through the afferent lymphatic vessel and settle in the T-cell–rich zones to present processed antigens to T cells. The net result of this process is an accumulation and concentration of the antigen in an environment that can be readily screened by infrequent antigen-specific T cells (see Fig. 44-2).

B cells are segregated from T cells in the lymph nodes and are localized in follicles. If B cells find their cooperating T cells, they enter germinal centers. Germinal centers contain a network of follicular dendritic cells that capture particulate antigen or immune complexes on the cell surface. This unprocessed antigen is taken up by antigen-specific B cells, processed and presented, and recognized by antigen-specific T cells. These T cells provide cytokines and cell-cell contact signals to support the germinal center reaction, a process that includes somatic hypermutation, affinity selection, and isotype switching (see Fig. 44-5). Germinal centers are essential for generating antibody-secreting plasma cells and memory B cells.

Lymphoid organ development is highly dependent on environmental cues. The symbiotic relationship between the host immune system and microorganisms is best exemplified in the gastrointestinal tract. Development of gut-associated lymphoid tissue is absolutely dependent on bacterial colonization. Increasing evidence suggests that host-symbiont interactions regulate adaptive immune functions throughout life. Disturbances in the bacterial microbiota and failure to maintain intestinal homeostasis are important in diverse diseases, including inflammatory bowel disease (Chapter 143) and HIV-associated immune defects.

Memory

An important consequence of adaptive immunity is the generation of immunologic memory, the basis for long-lived protection after a primary infection. Memory induction by vaccination is one of the landmark successes in medicine. Immunologic memory is defined as the ability to respond more rapidly and effectively to pathogens that have been encountered previously. The bases of immunologic memory are qualitative and quantitative changes in antigen-specific T cells and B cells. As a direct result of clonal expansion and selection in antigen-driven responses, the frequencies of antigen-specific memory B cells and memory T cells are increased 10-fold to 1000-fold compared with the naïve repertoires. The mechanisms through which memory T cells and B cells escape clonal downsizing in the terminal stages of the primary immune response are not clear. The enrichment of antigen-specific B cells and T cells enhances the sensitivity of the system to renewed challenges and provides a head start of 4 to 10 cell divisions. In addition to increased frequencies, memory T cells and B cells are functionally different from their naïve counterparts. Memory cells are long-lived and survive in the presence of certain cytokines without the need for continuous antigenic stimulation, guaranteeing immunologic memory for the life expectancy of the individual cell. Memory B cells produce predominantly IgG and IgA antibodies with evidence of somatic hypermutation and high affinity for the antigen. Cell surface expression of high-affinity antibodies allows more efficient antigen uptake, which enhances the crucial interaction with T cells. High affinity also gives memory B cells a competitive advantage over naïve B cells in antigen binding, leading to progressive affinity maturation of somatically mutated antibody molecules.

Because the TCR does not undergo isotype switching or affinity maturation, memory T cells are more difficult to distinguish from naïve or effector T cells. In contrast to effector cells, memory T cells lack activation markers and need antigen stimulation to resume effector functions. In contrast to naïve T cells, memory T cells have a lower activation threshold and are less dependent on costimulatory signals. In essence, their requirements for antigen stimulation are fewer, and their clonal size is larger, permitting fast, efficient responses to secondary antigen encounters. Also, memory T cells resume effector functions without having to undergo cell divisions.

Immunologic Tolerance and Autoimmunity

Unresponsiveness to self is a fundamental property of the immune system and is a condition, sine qua non, to maintain tissue integrity of the host. Self/nonself distinction is relatively straightforward for the innate immune system, in which receptors to nonself molecules are genetically encoded and evolutionarily selected. Self/nonself discrimination is much more complex for the adaptive immune system, in which antigen-specific receptors are generated randomly and the entire spectrum of antigens can be recognized. The adaptive immune system must acquire the ability to distinguish between self and nonself. Several different mechanisms are used, collectively called *tolerance*. Tolerance is antigen specific; its induction requires the recognition of antigen by lymphocytes in a defined setting. Failure of self-tolerance results in immune responses against self-antigens. Such reactions are called *autoimmunity* and may give rise to chronic inflammatory autoimmune disease.

Central and peripheral tolerance mechanisms can be distinguished. In central tolerance, self-reactive lymphocytes are deleted during development. This process of negative selection is particularly important for T cells. During thymic development, T cells that recognize antigen with high affinity, in particular antigens that are constitutively expressed on antigen-presenting cells, are deleted. Central tolerance for B cells follows the same principles. Recognition of antigen by developing B cells in the bone marrow induces apoptosis. Negative selection is particularly important for B cells that recognize multivalent antigens because they do not depend on T-cell help and cannot be controlled peripherally.

Not all self-reactive T cells are centrally purged from the repertoire; certain antigens are not encountered at sufficient densities in the thymus. Also, all T cells have some degree of self-reactivity, which is necessary for positive selection in the thymus and for peripheral survival. Mechanisms of peripheral T-cell tolerance include anergy, peripheral deletion, clonal ignorance, and suppression of immune responses by regulatory T cells. T-cell anergy is transient and is actively maintained. It is induced if $CD4^+$ T cells recognize antigens without receiving costimulatory signals. In general, costimulatory molecules are restricted to antigen-presenting cells, and their expression is activation dependent. Antigen recognition on immature or resting antigen-presenting cells or on any cell other than peripheral antigen-presenting cells results in anergy. Tissue-residing immature dendritic cells need to be activated by cytokines or recognition of PAMPs to stimulate and not to anergize T cells. Peripheral deletion is induced as a consequence of hyperstimulation. Hyperstimulation of T cells (e.g., by high doses of antigen and high concentrations of IL-2) preferentially activates pro-apoptotic pathways and causes elimination of the responding T-cell specificity. This mechanism may be responsible for the elimination of T cells specific for plentiful peripheral self-antigens and for foreign antigens abundantly present during infection. Whereas induction of anergy and activation-induced cell death are active consequences of antigen recognition, the third tolerance mechanism, clonal ignorance, is less well understood. Clonal ignorance is defined as the presence of self-reactive lymphocytes that fail to recognize or to respond to peripheral antigens. These cells remain responsive to antigenic challenge if given in the right setting. An example of clonal ignorance is nonresponsiveness to sequestered antigens that are not accessible to the immune system. Other mechanisms must exist, however, because clonal ignorance has also been shown for accessible antigens. Treg cells play a pivotal role in maintaining peripheral tolerance. During an immune response, T cells can acquire the ability to produce regulatory cytokines, such as TGF-β, IL-10, or IL-4, that dampen or suppress immune responses. A dedicated subset of Treg cells, $Foxp3\ CD4^+$ T cells, has been identified and characterized. Harnessing the frequencies and function of these cells may offer a promising approach to restoring peripheral tolerance in treating autoimmune diseases or facilitating transplantation tolerance; their elimination or functional suppression may potentiate cancer immunotherapy.

Peripheral tolerance of B cells is maintained through the absence of T-cell help. B cells require signals from T cells to differentiate into effector cells. B lymphocytes that recognize self-antigens in the periphery in the absence of T-cell help are rendered anergic or are unable to enter lymphoid follicles, where they could receive T-cell help, effectively excluding them from immune responses.

Generation and maintenance of self-tolerance can fail, in which case autoimmune responses are generated. Overall, chronic inflammatory diseases

induced by tolerance failure occur in about 5% of the general population. Given the complexity of regulation, it is surprising that autoimmune diseases are not more frequent. It is thought that most autoimmune diseases result from dysfunction of the adaptive immune system. Many models of autoimmunity rely on the hypothesis that peripheral anergy is broken. Aberrant expression of costimulatory molecules on nonprofessional antigen-presenting cells or inappropriate activation of tissue-residing dendritic cells sets the stage for the induction of "forbidden" T-cell responses. Also, autoreactive B cells that recognize self-antigen complexed with foreign antigen may engulf this complex and receive help from T cells specific for the foreign antigen. Autoimmunity also may emerge if antigen ignorance is broken. This could happen if tissue barriers break down and antigens that are usually sequestered from the immune system, such as antigens from the central nervous system or the eye, become accessible. Tolerance mechanisms of anergy or clonal ignorance can also fail if a foreign antigen is sufficiently different from a self-antigen to initiate an immune response but sufficiently similar for activated T cells to elicit T-cell and B-cell effector functions (molecular mimicry).

THE MAJOR HISTOCOMPATIBILITY COMPLEX

PETER K. GREGERSEN

HUMAN LEUKOCYTE ANTIGENS

The major histocompatibility complex (MHC) occupies a unique position in the nexus of clinical medicine, immunology, and genetics. Hundreds of diseases and clinical phenotypes have been associated with genes located within the MHC. The most important of these genes encode the human leukocyte antigens (HLAs), a family of cell surface proteins that are essential for normal immune function. HLA genes display a remarkably high degree of genetic variation among individuals in the population, and this variability is largely responsible for individual differences in immune responsiveness. These effects on immune responsiveness are in turn related to individual differences in susceptibility to a variety of autoimmune, inflammatory, and infectious disorders. Thus, the structural variability of the HLA molecules themselves underlies most but not all of the HLA disease associations reported over the past 3 decades.

Structure of HLA Molecules

Discovery of the x-ray crystallographic structure of an HLA molecule had a major impact on understanding the molecular basis of immune recognition by T cells. A ribbon diagram of the structure of an HLA class I molecule is shown in Figure 45-1. The "business end" of the molecule contains a peptide-binding cleft formed by the two membrane distal domains (α_1 and α_2) of the HLA class I heavy chain, as seen in the side view in Figure 45-1A. A view from the top of this cleft is shown in Figure 45-1B, which can be thought of as the "T-cell view" of the HLA molecule. It illustrates that the base of the peptide-binding cleft is formed by β-pleated sheets, with two α-helical structures forming the sides of the cleft. It is now known that the T-cell receptor physically interacts with both the HLA molecule and the peptide bound within the cleft to form a "trimolecular complex" (E-Fig. 45-1). Thus, it is not surprising that structural differences in HLA molecules, particularly in amino acids surrounding the peptide-binding cleft, have a major role in many immunologically mediated diseases.

Properties of HLA Class I and Class II Isoforms

There are two major isoforms of HLA molecules, termed *class I* and *class II*. Both isoforms are anchored in the cell membrane and contain a peptide-binding cleft similar to that shown in Figure 45-1. However, their specific structural and functional features differ, as summarized in Table 45-1 (E-Fig. 45-2). In the case of class I molecules, a highly variable α chain (45 kD) forms a noncovalent heterodimer with an invariant β_2-microglobulin (12 kD) and is anchored to the cell by a single transmembrane segment on the α chain. In contrast, HLA class II molecules are formed by α chain (32 kD) and β chain (28 kD) heterodimers, and in many cases both chains exhibit structural variability among individuals. HLA class I molecules are expressed on nearly all nucleated cells. HLA class II molecules are found on more restricted cell populations, including B cells, monocytes, macrophages, dendritic cells, and other "professional" antigen-presenting cells such as Langerhans cells in the skin. Certain subsets of T cells also express class II molecules. In addition, HLA class II molecules are expressed on thymic epithelium, where they are involved in thymic selection of the T-cell receptor repertoire (see later). The size of the peptides bound to HLA class I molecules is

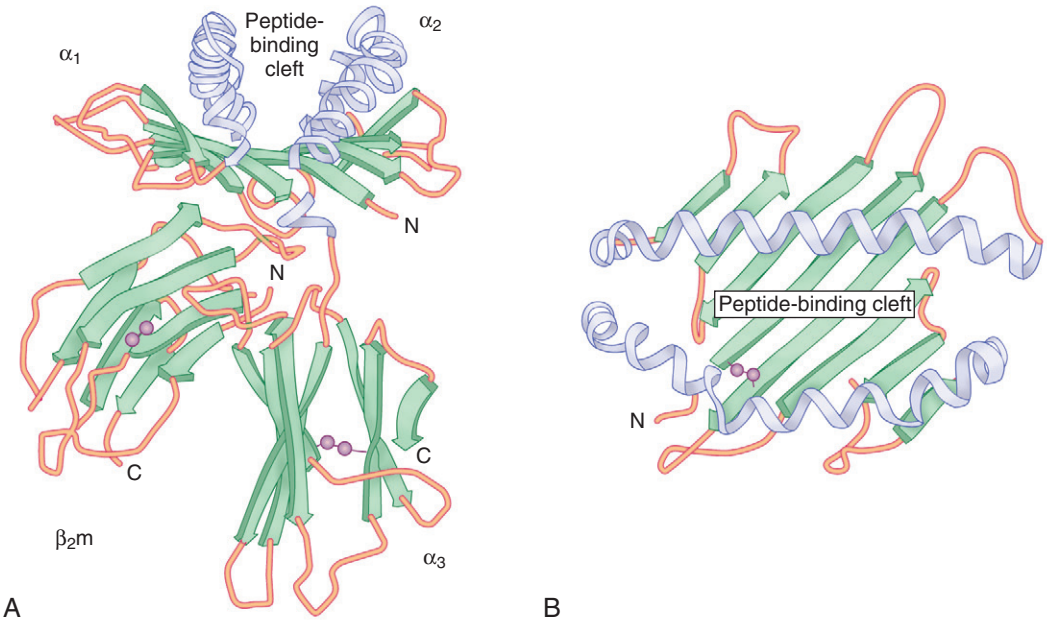

FIGURE 45-1. Two views of an HLA class I molecule. A, Ribbon diagram showing the x-ray crystallographic structure of an HLA class I molecule (side view). The β-strand structures are indicated by *thick green arrows* (oriented in an amino to carboxy direction), whereas connecting loops are indicated as *thin lines*. The α-helices are shown flanking a peptide-binding cleft at the top (membrane distal portion) of the molecule. The base (membrane proximal portion) of the molecule is formed by the noncovalent association between the α_3 domain of the class I α chain and β_2-microglobulin (β_2m). **B,** View from the top of the molecule emphasizing that the base of the peptide-binding cleft consists of β-pleated sheets flanked by α-helical structures. C = C terminal; N = N terminal. (Adapted from Bjorkman PJ, Saper MA, Samraoi B, et al. Structure of the class I histocompatibility antigen HLA-A2. *Nature*. 1987;329:506-512.)

circumscribed to 8 or 9 amino acids in length, whereas the peptides presented by HLA class II molecules are longer and more variable in size, with lengths usually ranging from 10 to 20 amino acids. HLA class I molecules generally present peptides for recognition by $CD8^+$ T cells, such as in cytotoxic $CD8^+$ T-cell responses against virally infected tissues. In contrast, HLA class II molecules are primarily involved in presenting antigenic peptides to $CD4^+$ T cells.

TABLE 45-1 COMPARISON OF STRUCTURAL AND FUNCTIONAL FEATURES OF HLA CLASS I AND CLASS II ISOTYPES

FEATURE	HLA CLASS I	HLA CLASS II
Chain structure of heterodimer	45-kD α chain 12-kD β_2-microglobulin	34-kD α chain 28-kD β chain
Tissue distribution	All nucleated cells	Antigen-presenting cells (monocytes, B cells, dendritic cells, Langerhans cells), thymic epithelium, and some T cells; inducible on other cell types by interferon-γ
Size of bound peptides	8-9 amino acids	10-20 amino acids
Source peptides	Cytosolic	Endosomal
Functions	Presentation of antigenic peptides to $CD8^+$ T cells; ligands for natural killer cell receptors	Presentation of antigenic peptides to $CD4^+$ T cells

Sources of the peptide antigens presented by class I and class II molecules are quite distinct. In the case of class I molecules, the bound peptides are derived from cytosol and are loaded onto the class I molecules during their synthesis in the endoplasmic reticulum. Thus, either host or virally derived peptides may be present in the peptide cleft, and a peptide is required for proper folding and surface expression of class I molecules. In contrast, HLA class II molecules present peptides that are present in endosomes, and peptide loading onto class II molecules occurs in endocytic vesicles. These peptides are derived from sources exogenous to the cell, such as soluble proteins, particles, cell debris, or whole organisms. In the case of B cells, surface immunoglobulin can facilitate the internalization of highly specific antigens, whereas in macrophages and other antigen-presenting cells, endocytosis and phagocytosis mediate less specific cellular internalization of antigens. Mycobacteria and intracellular parasites such as *Leishmania* replicate inside vesicular compartments of the cell; therefore, peptides from these agents are generally presented on class II molecules.

Organization of HLA Molecules

Genetic Map of HLA Genes

The MHC is contained within a 3.6 million–base pair region located at chromosome 6p21 and encodes more than 200 different genes, approximately 40% of which appear to have some role in immune function. Figure 45-2 shows a simplified map of the major HLA loci. The HLA class I and class II regions are separated by a gene-dense region often referred to as the *central* MHC. This central region encodes a number of genes of immunologic importance, including several complement components and tumor necrosis factor-α and -β, to name only a few. The class I heavy chains for HLA-A, HLA-B, and HLA-C are encoded on the telomeric side of the MHC, along with a number of other class I–like molecules, as shown in Figure 45-2. The HLA class II region is considerably more complicated, with multiple α and

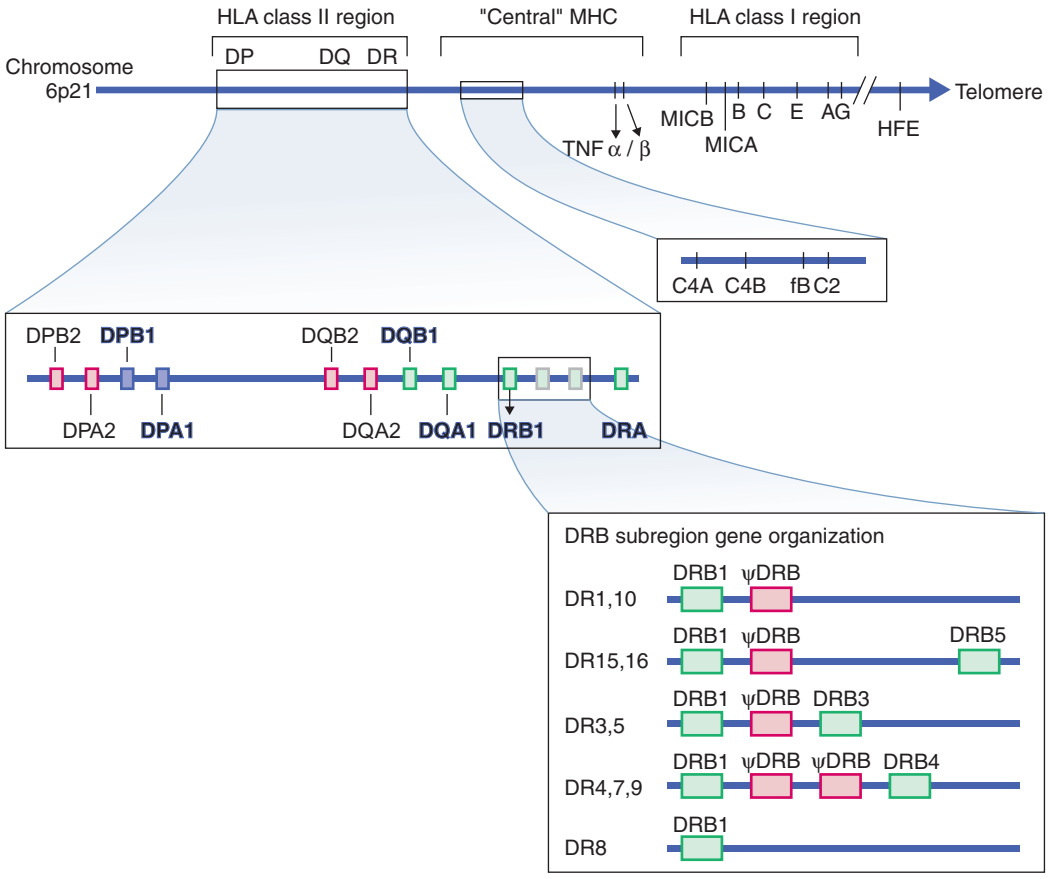

FIGURE 45-2. Map of the human major histocompatibility complex (MHC) spanning approximately 3.5 million base pairs on the short arm of chromosome 6. The HLA class I and class II molecules are encoded in distinct regions of the MHC. The HLA class II region contains three subregions: DR, DQ, and DP. Each of these subregions contains a variable number of α- and β-chain genes. HLA class II loci with known functional protein products are labeled in bold. In the case of DR, different numbers of DRB genes are present in different haplotypes, some of which are nonfunctional pseudogenes (ψ). A summary of the most common of these is shown in the *box*. The DQ and DP subregions each contain one pair of functional α- and β-chain genes. The HLA class I region contains the three "classic" class I genes—HLA-A, HLA-B, and HLA-C—as well as other related "nonclassic" class I molecules such as MICA, MICB, HLA-E, and HLA-G. The gene for familial hemochromatosis (HFE) is found just telomeric to the HLA class I region, about 3 million base pairs distant from HLA-A. The "central" MHC also contains a number of genes related to immune function, including the complement components (C4A, C4B, C2, and factor B), as well as tumor necrosis factor (TNF)-α and -β. Not shown in the figure are more than 100 additional genes, many of which are located in the central MHC. A complete listing of MHC-encoded genes can be found in Horton R, Wilming L, Rand V, et al. Gene map of the extended human MHC. *Nat Rev Genet*. 2004;5:889-899.

β chains encoded for each of the major HLA class II isotypes: HLA-DR, HLA-DQ, and HLA-DP. Of these, HLA-DR exhibits additional complexity, in that a different gene organization of β chains is seen, depending on the particular DR haplotype.

HLA Typing Nomenclature and Patterns of Allelic Sequence Variation

In addition to the organizational complexity of the HLA region, the nomenclature for HLA typing of different alleles at each locus presents some challenges for the nonexpert. In the past decade, hundreds of HLA alleles have been sequenced, and each HLA allelic variant is defined by its locus and sequence. For example, B*2701 indicates allele 2701 at the HLA-B locus, and DRB1*0401 indicates allele 0401 at the DRB1 locus. This nomenclature is, in principle, quite straightforward. However, there are many different alleles at each of these loci; for example, more than 100 alleles have been identified at the HLA-B locus, and similar allelic diversity is seen at HLA-A and HLA-C, as well as in many of the HLA class II loci. The sequence relationships between alleles are both complex and informative for understanding HLA associations with disease, and the nomenclature reflects this to some degree. It is therefore worth understanding the origins of these naming conventions.

The current HLA nomenclature contains traces of the early history of HLA typing. A serologic approach was initially used for HLA typing. HLA protein variation is highly immunogenic between individuals; therefore, typing alloantisera can be derived either from multiply transfused individuals (who make an antibody response to HLA molecules on the donor white cells) or from multiparous women (who commonly form antibodies to the paternal HLA antigens expressed by the fetus). Thus, by screening large numbers of individuals, panels of alloantisera were developed as the first HLA typing reagents. These original HLA typing sera did not distinguish all the variation at a particular locus, and it is now apparent that serologic typing actually detects rather large groups of structurally related alleles. For example, the serologically defined allele HLA-DR4 contains well over 30 different alleles at the DRB1 locus, although only a few of these alleles are common in the population. Table 45-2 summarizes the major allelic groups at the DRB1 locus and shows the relationship between the original serologic typing and the various groups of alleles defined at the sequence level. For some allelic groups, such as HLA-DR3, there is little sequence diversity within the group, depending on the population; thus, almost all white Europeans carry just one type of DR3 allele, DRB1*0301. As a result, the term *DR3* is often used in conversation to refer to the DRB1*0301 allele and is reasonably precise when talking about a white population. In contrast, *DR4* could refer to any one of several different alleles (see Table 45-2).

In addition to having large numbers of alleles at each locus, the frequency distribution of these alleles is highly variable in human populations. As shown in Table 45-2, five DRB1 alleles predominate in the northern European white population (shown in bold), with frequencies ranging from 10 to 30%. This frequency distribution would be quite different in a different population group, even among white subgroups, such as a comparison of northern and southern European populations. The population differences emphasize the importance of matching controls to cases by ethnic origin when comparing allele frequencies between them.

TABLE 45-2 SUMMARY OF MAJOR ALLELIC GROUPS AT THE DRB1 LOCUS AND THEIR RELATIONSHIP TO COMMON DRB1 ALLELES DEFINED AT THE SEQUENCE LEVEL

Allelic Groups (Serologic Typing)		
MAJOR GROUPS	**SEROLOGIC "SPLITS"**	**EXAMPLES OF COMMON ALLELES (NORTHERN EUROPEAN WHITE INDIVIDUALS) DEFINED BY SEQUENCE***
DR1		DRB1***0101**, 0102, 0103
DR2	DR15 DR16	DRB1***1501**, 1502 DRB1*1601
DR3		DRB1***0301**
DR4		DRB1***0401**, 0402, 0403, 0404, 0405, 0406, 0407, 0408
DR5	DR11 DR12	DRB1*1101, 1102, 1103, 1104 DRB1*1201
DR6	DR13 DR14	DRB1*1301, 1302, 1303 DRB1*1401
DR7		DRB1***0701**
DR8		DRB1*0801, 0802, 0803, 0804, 0806
DR9		DRB1*0901
DR10		DRB1*1001

*Alleles in bold are found in at least 10% of individuals in the population.

HLA Associations with Disease: The Concept of Disease Susceptibility

Table 45-3 provides a representative sample of some well-established HLA associations with human disease. The overwhelming majority of these studies were conducted with a case-control design in which the frequency of alleles was compared in subjects with appropriately matched controls. Matching of controls is a critical part of the study design because HLA alleles can differ greatly between different populations; as a result, many early reports in the literature turned out to be false positives. Nevertheless, hundreds of diseases and medically relevant phenotypes have confirmed associations with HLA alleles.

As shown in Table 45-3, the strength of many of these disease associations is rather modest, with an estimated relative risk of 10 or less. Therefore, HLA alleles confer a state of susceptibility, or risk, for disease. Because the HLA risk alleles are usually quite common in the population, and the diseases are relatively uncommon, many individuals who carry these risk alleles do not contract the disease. Conversely, a substantial number of individuals with the disease do not carry the known HLA risk-conferring alleles. Thus, in a practical sense, HLA typing alone is not very useful in a clinical setting for most diagnostic purposes. Even for a disease such as ankylosing spondylitis (Chapter 273), where the relative risk approaches 100, the disease develops in only a fraction of the HLA-B27 carriers in the population because the carrier frequency of HLA-B27 in a white population is approximately 8%. When confronting a patient with typical symptoms of ankylosing spondylitis, testing for B27 can be confirmatory; however, it is not diagnostic by itself because the prevalence of ankylosing spondylitis is very low (≈0.12%) in the population. The recently described association of B57 with adverse reactions to abacavir is one of the first examples in which HLA testing may be directly useful in a clinical setting. Knowledge of this association has now been shown to reduce the incidence of drug reactions in treated populations.

This pattern of association, in which HLA alleles confer a state of risk or susceptibility to disease, implies that other factors must be involved for a disease to actually manifest. In general, these other factors can include other genes, environmental factors, and nongenetic factors such as stochastic or "epigenetic" events that may occur at any time during development. Somatic rearrangements of T-cell and B-cell receptor genes are one example of such a stochastic process. These factors explain why concordance rates for many autoimmune disorders in monozygotic twins are only in the 30% range, even though these diseases all exhibit significant genetic associations with particular HLA alleles and have a strong genetic component. The genetic predisposition conferred by the MHC is only part of the overall genetic contribution to most autoimmune disorders, and the MHC component varies in importance, depending on the particular disease.

Linkage Disequilibrium

An understanding of the concept of linkage disequilibrium is critical to the proper interpretation of HLA associations or, indeed, any genetic associations with human diseases. The term *linkage disequilibrium* is used to describe the fact that alleles at adjacent loci are often found together on the same chromosomal segment, or haplotype, more frequently than would be predicted by chance. This phenomenon occurs throughout the genome, and the MHC is no exception. Indeed, because of the high degree of allelic diversity at HLA loci, the pattern of linkage disequilibrium between HLA alleles can be quite complicated and, like the alleles themselves, often varies among different population groups. For example, in most white populations, the DRB1*0301 allele is almost always found on the same haplotype with the DQB1*0201 allele at the DQB1 locus. (Note that the DQB1 locus is situated several hundred thousand base pairs away from the DRB1 locus; see Fig. 45-2.) Likewise, DR4 alleles (at DRB1) are often found to be in linkage

TABLE 45-3 SELECTED HLA ASSOCIATIONS WITH HUMAN DISEASES

DISEASE	MAJOR HLA ASSOCIATION (ALLELIC GROUP OR HAPLOTYPE)	EFFECT/APPROXIMATE RELATIVE RISK/RELATIVE HAZARD
AUTOIMMUNE DISEASES		
Type 1 diabetes	DR3-DQ2 DR4-DQ3	10
Multiple sclerosis	DR2-DQ1	3-5
Celiac disease	DR3-DQ2 DR4-DQ3	30
Rheumatoid arthritis	DR1, DR4	2-5
Systemic lupus erythematosus	DR2, DR3, DR8	2-10
Ankylosing spondylitis	B27	100
Psoriasis	Cw6	10
INFECTIOUS DISEASES		
Progression to AIDS	B35	2-3
Severe malaria	B53	0.5 (protective)
Transient vs persistent hepatitis C infection	DR11-DQ3	5-10
OTHER		
Hemochromatosis	A3	10
Adverse drug reaction (allopurinol)	B58	>100
Cervical cancer	DR11-DQ3	2-3

AIDS = acquired immunodeficiency syndrome; HFE = hereditary hemochromatosis gene.

disequilibrium with DQB1*0302. These two haplotypes are both associated with type 1 diabetes (see Table 45-3).

Occasionally, linkage disequilibrium can extend to very long chromosomal segments. For example, a common haplotype in northern European white populations extends to several million base pairs and contains the HLA alleles A*0101-B*0801-DRB1*0301-DQB1*0201, often referred to as the *A1-B8-DR3* or *8.1 haplotype*. This particular haplotype accounts for about a third of all DR3 haplotypes in a U.S. white population and is of particular interest because it is associated with a variety of diseases, some of which are listed in Table 45-4. Because haplotypes such as these are inherited as a unit, it can be difficult to determine which specific genes on the haplotype are actually responsible for the disease association in a population.

There are a number of possible explanations for linkage disequilibrium. In part, it reflects the fact that meiotic recombination in the genome is discontinuous, and some loci have very low recombination rates between them—such as between the DRB1 and DQB1 loci. In addition, population migrations can introduce haplotypes into new population groups and thereby generate common "founder" haplotypes. Finally, some haplotypes may be kept intact because of selection. For example, it may be that the combination of genes found on the A1-B8-DR3 haplotype confers a survival advantage. Whatever the underlying reason, it is important to keep in mind that any HLA association may reflect the presence of linkage disequilibrium with another allele at another locus on the same haplotype.

HLA Associations with Autoimmune and Infectious Diseases

The majority of autoimmune disorders exhibit some association with HLA class II alleles, although because of linkage disequilibrium, it is not always clear which locus is actually responsible for the association. In the case of type 1 diabetes, the bulk of evidence suggests that alleles at the HLA-DQ locus play a predominant role by virtue of specific amino acid substitutions that are present on multiple different DQB1 alleles; aspartic acid at amino acid position 57 of the DQβ chain is thought to be of particular importance. Rheumatoid arthritis is another autoimmune disorder in which the molecular basis of HLA class II associations has been partially worked out. In this case, a series of DRB1 alleles, including DRB1*0101, *0401, *0404, *0405, all share a common amino acid sequence (Q-K or R-R-A-A) at positions 70 to 74 of the DRβ1 chain, located on the rim of the peptide-binding cleft (see Fig. 45-1). This sequence is known as the *shared epitope* and provides an appealing unifying explanation for the complex patterns of HLA-DR associations with rheumatoid arthritis. However, for both type 1 diabetes and rheumatoid arthritis, there are exceptions to these observations, and certain combinations of HLA alleles can confer very high degrees of risk. For most of the HLA-associated diseases, the exact molecular basis of the association has not been definitively established, and in some cases, even the causative locus is uncertain (see Table 45-3). For ankylosing spondylitis, it appears that most allelic variants of HLA-B27 are associated with disease. Recent genetic data provide support for the C*0601 allele being causative for psoriasis. However, in the case of systemic lupus erythematosus and multiple sclerosis, the relative importance of DRB1 versus DQB1 alleles is not clear.

For infectious diseases, such as the role of HLA-B35 in the progression of acquired immunodeficiency syndrome (AIDS), there is evidence that particular amino acid residues on the HLA-B molecule are especially important. The amino acids that distinguish risk alleles (B*3502, B*3503) from nonrisk alleles (B*3501) alter the structure of a "pocket" within the peptide-binding cleft on the various HLA-B35 proteins and therefore can affect the kinds of human immunodeficiency virus (HIV) antigenic peptides that are bound by these alleles. Other HLA-B alleles, such as B27 and B58, protect against progression of HIV, apparently by similar mechanisms. Aside from HLA-B associations with HIV outcome, specific structural explanations have not yet been defined for most HLA associations with infectious diseases.

TABLE 45-4 DISEASES AND PHENOTYPES ASSOCIATED WITH THE A1-B8-DR3 (8.1) HAPLOTYPE

IgA deficiency
Common variable immunodeficiency
Myasthenia gravis
Dermatitis herpetiformis
Rheumatoid arthritis (central portion of the 8.1 haplotype only)
Rapid loss of $CD4^+$ T cells in HIV infection
Low antibody response to hepatitis B immunization
Increases (tumor necrosis factor) or decreases (interleukin-5) in cytokine production in vitro

Mechanisms Explaining HLA Associations with Disease

It is fair to say that the mechanisms underlying HLA disease associations are still not fully explained for any disorder, and the mechanisms clearly differ for different diseases. However, there are two general categories of mechanisms that are likely to be important. First, a pattern of immune responsiveness, or lack of immune responsiveness, can be related to the ability of an individual's HLA molecules to bind and present antigenic peptides (either foreign or self) to T cells. This mechanism is often referred to as *determinant selection*, which means that HLA molecules are involved in selecting which antigenic determinants are selected for presentation to responding T cells. As mentioned earlier, this probably underlies the contrasting HLA-B allelic associations with AIDS progression.

An alternative mechanism invokes the role of HLA molecules in regulating thymic selection of the mature T-cell repertoire. During thymic development, thymocytes either survive or die of apoptosis, depending in large part on their ability to recognize "self" HLA molecules (and associated "self" peptides) on thymic epithelium or on other antigen-presenting cells in the thymus. This recognition is mediated through the α/β T-cell receptor. Thus, the structural repertoire of T-cell receptors in the mature circulating T-cell population is shaped by the structural variation of the selecting HLA molecules. This may lead to "holes" in the T-cell repertoire or, alternatively, enrichment for particular T-cell specificities. In this view, the presence of particular sets of potentially responding T cells provides a risk factor for response, or lack of response, to autoantigens or foreign antigens. It implies the need for an environmental trigger to actually cause this risk to manifest as overt clinical disease.

In addition to these two basic models, it has been proposed that HLA molecules can themselves serve as a source of antigenic peptides and may predispose to disease by means of molecular mimicry or other more complex mechanisms. However, none of these proposed mechanisms has been definitively proved for any disorder.

HLA Associations with Disease May Reflect Linkage Disequilibrium with Non-HLA Genes

In most cases, HLA associations such as those listed in Table 45-3 probably reflect the mechanistic involvement of the HLA molecules themselves in the disease or phenotype under study. However, the MHC is one of the most gene-dense segments in the human genome, and other genes in the region may in fact be responsible for the observed disease association. A good example of this is hemochromatosis (Chapter 219). Early studies showed that certain HLA class I alleles, such as HLA-A3, were highly associated with this disorder. However, it is now clear that the causative gene, *HFE*, is actually more than 3 million base pairs distant from the HLA-A locus (see Fig. 45-2). The HLA-A3 association is observed because the *HFE* C282Y allele (causative for hemochromatosis) is frequently found on the same haplotype as HLA-A3 in many white populations.

Some of the associations with the A1-B8-DR3 haplotype almost certainly reflect linkage disequilibrium with genes other than HLA class I and class II genes (see Table 45-3). Although the HLA genes may contribute to some of these disorders, it is likely that other genes on the 8.1 haplotype also contribute to risk. The central portion of the MHC in particular (see Fig. 45-2) is very dense with many genes of uncertain function, as well as genes for important inflammatory cytokines such as tumor necrosis factor and complement components C2 and C4. Indeed, the combination of several different genes may well explain why this haplotype is associated with so many different immunologic disorders.

HLA Typing and Bone Marrow Transplantation

As the term *histocompatibility* implies, the ability of the MHC to control graft rejection in experimental animals led to the realization that HLA matching is important for transplant survival. For solid organ transplantation, treatment with immunosuppressive agents often prevents the rejection of HLA-mismatched transplants. However, for bone marrow transplantation (Chapter 181), careful matching of the major HLA class I and class II loci is important for a successful outcome, regardless of whether the donor is related or unrelated to the recipient. Because of the extensive sequence diversity of HLA alleles, very large numbers of unrelated donors are required to ensure a reasonable probability of a match for any given recipient who does not have a living related donor. This has led to the development of international bone marrow donor registries that now contain more than 10 million potential donors who have been screened for HLA type. If transplantation is performed in the presence of a significant mismatch at either class I or class II loci, T cells from the recipient may recognize the donor HLA molecules or their bound peptides as foreign and initiate an immune response, leading to graft rejection. Interestingly, even when HLA molecules are completely matched, T cells still occasionally initiate rejection because of individual differences in "minor" histocompatibility antigens that are not encoded within the MHC but are processed and presented as antigenic peptides that appear foreign to the host.

HLA Class I: Alternative Forms and Functions

The HLA class I region of the MHC contains a number of genes that encode so-called nonclassic class I genes, including HLA-E, HLA-G, MICA, and MICB (see Fig. 45-2). These molecules do not present peptides to α/β T cells but rather interact with a variety of other ligands that are generally found on natural killer cells and some other types of T cells. In addition, certain allelic subsets of the "classic" class I molecules (e.g., HLA-A, -B, and -C) can interact with some of these other ligands. Among these ligands, the killer cell immunoglobulin-like receptor (KIR) family displays a large degree of genetic variation in both gene structure and gene number and has been associated with human disease. For example, certain combinations of HLA class I alleles and KIR alleles have been associated with risk for rheumatoid vasculitis as well as outcome of HIV infection. These genetic relationships are complex, and this aspect of HLA class I function in disease has been relatively understudied.

HLA and Clinical Medicine

The identification of risk genes within the MHC may hold the key to understanding a large number of immunologically related disorders. However, we are far from identifying all of these genes, and in the few cases in which the actual risk alleles are known with confidence, their mechanism of action is not clear. Moreover, most HLA-associated disorders are complex, and additional genetic or environmental factors (or both) are likely to be involved, most of which have not yet been identified. Therefore, in most cases, HLA typing alone has limited diagnostic utility. HLA typing may be diagnostically important in the future if used in combination with other biomarkers, and HLA typing remains critical to successful bone marrow transplantation. Thus, it is likely that future advances in immunology and genetics will lead to greater clinical use of genetic typing of HLA genes, as well as other genes, within the MHC.

MECHANISMS OF IMMUNE-MEDIATED TISSUE INJURY

JANE E. SALMON

THE ADAPTIVE IMMUNE RESPONSE

Definition

The adaptive immune response is a crucial component of host defense against infection. Its distinguishing and unique feature is the ability to recognize pathogens specifically, based on clonal selection of lymphocytes bearing antigen-specific receptors. Antigens unassociated with infectious agents also may elicit adaptive immune responses. Many clinically important diseases are

characterized by normal immune responses directed against an inappropriate antigen, typically in the absence of infection. Immune responses directed at noninfectious antigens occur in allergy, in which the antigen is an innocuous foreign substance, and in autoimmunity, in which the response is to a self-antigen.

Effector mechanisms that eliminate pathogens in adaptive immune responses are essentially identical to those of innate immunity. The specific antigen recognition feature of the adaptive immune response seems to have been appended to the preexisting innate defense system. As a result, the inflammatory cells and molecules of the innate immune system are essential for the effector functions of B and T lymphocytes. In addition to initiating protective responses, they mediate tissue injury in allergy, hypersensitivity, and autoimmunity.

Effector Mechanisms

Effector actions of antibodies depend on recruiting cells and molecules of the innate immune system. Antibodies are adapters that bind antigens to nonspecific inflammatory cells and direct their destructive effector responses. Antibodies also activate the complement system, which enhances opsonization of antigens, recruits phagocytic cells, and amplifies (or "complements") antibody-triggered damage. The isotype or class of antibodies produced determines which effector mechanisms are engaged.

Cell-bound receptors for immunoglobulin (Ig) constitute the link between humoral and cellular aspects of the immune cascade and play an integral part in the process by which foreign and endogenous opsonized material is identified and destroyed. These cell-based binding sites for antibodies, termed *Fc receptors,* interact with the constant region (Fc portion) of the immunoglobulin heavy chain of a particular antibody class regardless of its antigen specificity. Accessory cells that lack intrinsic specificity, such as neutrophils, macrophages, and mast cells, are recruited to participate in inflammatory responses through the interaction of their Fc receptors with antigen-specific antibodies. Distinct receptors for different immunoglobulin isotypes are expressed on different effector cells.

Receptors for IgG (FcγRs) are a diverse group of receptors expressed as hematopoietic cell surface molecules on phagocytes (macrophages, monocytes, neutrophils), platelets, mast cells, eosinophils, and natural killer (NK) cells. FcγRs often are expressed as stimulatory and inhibitory pairs. Triggering of stimulatory FcγRs initiates a series of events, including phagocytosis; antibody-dependent, cell-mediated cytotoxicity; secretion of granules; and release of inflammatory mediators, such as cytokines, reactive oxidants, and proteases. Extensive structural diversity among FcγR family members leads to differences in binding capacity, signal transduction pathways, and cell type–specific expression patterns. This diversity allows IgG complexes to activate a broad program of cell functions relevant to inflammation, host defense, and autoimmunity. Phagocyte activation is triggered by stimulatory FcγRs, facilitating the recognition, uptake, and destruction of antibody-coated targets, whereas multivalent IgG binding to FcγRs on platelets leads to platelet aggregation and thrombosis, and binding to FcγRs on NK cells mediates cytotoxicity of antibody-coated targets.

IgE binds to high-affinity FcεRs on mast cells, basophils, and activated eosinophils. In contrast to FcγRs, which are low affinity and bind to multivalent IgG rather than circulating individual IgG molecules, FcεRs can bind monomeric IgE. A single mast cell may be armed with IgE molecules specific for different antigens, all bound to surface FcεRs. Mast cells, localized beneath the mucosa of the gastrointestinal and respiratory tracts and the dermis of the skin, await exposure to multivalent antigens, which cross-link surface IgE bound to FcεRs and cause release of histamine-containing granules and generation of cytokines and other inflammatory mediators. IgE-mediated activation of eosinophils, cells normally present in the connective tissue of underlying respiratory, urogenital, and gut epithelium, leads to the release of highly toxic granule proteins, free radicals, and chemical mediators such as prostaglandins, cytokines, and chemokines. These amplify local inflammatory responses by activating endothelial cells and recruiting and activating more eosinophils and leukocytes. Prepackaged granules and high-affinity FcεRs that bind to free monomeric IgE enable an immediate response to pathogens or allergens at the first site of entry, a location where FcεR-bearing cells reside.

Inhibitory FcγRs, which modulate activation thresholds and terminate stimulating signals, are key elements in the regulation of effector function. Given that inhibitory and stimulatory Fc receptors are often coexpressed on the same cells, the effector response to a specific stimulus in a particular cell represents the balance between stimulatory and inhibitory signals. Inhibitory FcγRs can dampen responses triggered by FcεRs on mast cells and FcγR-mediated inflammation at sites of immune complex deposition.

Effector activities targeted by IgG and IgM also may be mediated by components of the complement system (Chapter 49). Antigen-bound multimeric immunoglobulin can initiate activation of the classical pathway of complement, causing enhanced phagocytosis of antigen-antibody complexes, increased local vascular permeability, and recruitment and activation of inflammatory cells. The target of injury is specified by the antibody, and the extent of damage is determined by the synergistic activities of immunoglobulin and complement.

Antigen-specific effector T cells also may initiate tissue injury. On exposure to an appropriate antigen, memory T cells are stimulated to release cytokines and chemokines that activate local endothelial cells and recruit and activate macrophages and other inflammatory cells. The effector cells directed by T-cell–derived cytokines, or cytolytic T cells themselves, mediate tissue damage. T_H1 cells produce interferon-γ (IFN-γ) and activate macrophages to cause injury, whereas T_H2 cells produce interleukin-4 (IL-4), IL-5, and eotaxin (an eosinophil-specific chemokine) and trigger inflammatory responses in which eosinophils predominate.

HYPERSENSITIVITY REACTIONS

In predisposed individuals, innocuous environmental antigens may stimulate an adaptive immune response, immunologic memory, and, on subsequent exposure to the antigen, inflammation. These "overreactions" of the immune system to harmless environmental antigens (allergens), called *hypersensitivity* or *allergic reactions,* produce tissue injury and can cause serious disease. Hypersensitivity reactions are grouped into four types according to the effector mechanisms by which they are produced (Table 46-1). The effectors for types I, II, and III hypersensitivity reactions are antibody molecules, whereas type IV reactions are mediated by antigen-specific effector T cells.

Autoimmune disease is characterized by the presence of antibodies and T cells specific for self-antigens expressed on target tissues. The mechanisms of antigen recognition and effector function that lead to tissue damage in autoimmune disease are similar to the mechanisms elicited in response to pathogens and environmental antigens. These mechanisms resemble certain hypersensitivity reactions and may be classified accordingly (Table 46-2). Autoimmune disease caused by antibodies directed against cell surface or extracellular matrix antigens corresponds to type II hypersensitivity reactions; disease caused by formation of soluble immune complexes that subsequently are deposited in tissue corresponds to type III hypersensitivity; and disease caused by effector T cells corresponds to type IV hypersensitivity. Typically, several of these pathogenic mechanisms are operative in autoimmune disease. However, IgE responses are not associated with damage in autoimmunity.

Type I Hypersensitivity Reactions

Type I hypersensitivity reactions (Fig. 46-1) are triggered by the interaction of antigen with antigen-specific IgE bound to FcεRs on mast cells, which causes mast cell activation. Proteolytic enzymes and toxic mediators, such as histamine, are released immediately from preformed granules, and chemokines, cytokines, and leukotrienes are synthesized after activation. Together, these mediators increase vascular permeability, break down tissue matrix proteins, promote eosinophil production and activation (IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor [GM-CSF]), and cause influx of effector leukocytes (tumor necrosis factor-α [TNF-α], platelet-activating factor, and macrophage inflammatory protein [MIP-1]), constriction of smooth muscle, stimulation of mucus secretion, and amplification of T_H2 cell responses (IL-4 and IL-13). Eosinophils and basophils, activated through cell surface FcεRs, rapidly release highly toxic granular proteins (major basic protein, eosinophil peroxidase, and collagenase) and, over a longer period, produce cytokines (IL-3, IL-5, and GM-CSF), chemokines (IL-8), prostaglandins, and leukotrienes that activate epithelial cells, leukocytes, and eosinophils to augment local inflammation and tissue damage.

FcεR-bearing effectors act in a coordinated fashion. The immediate allergic inflammatory reaction initiated by mast cell products is followed by a late-phase response that involves recruitment and activation of eosinophils, basophils, and T_H2 lymphocytes. The manifestations of IgE-mediated reactions depend on the site of mast cell activation. Mast cells reside in vascular and epithelial tissue throughout the body. In a sensitized host (an individual with IgE responses to antigens), re-exposure to antigen leads to type I hypersensitivity responses only in the mast cells exposed to the antigen. Inhalation of antigens produces bronchoconstriction and increased mucus secretion

TABLE 46-1 FOUR MAJOR TYPES OF IMMUNOLOGICALLY MEDIATED HYPERSENSITIVITY REACTIONS*

IMMUNOLOGIC SPECIFICITY	TYPE I (IgE ANTIBODY)	TYPE II (IgG ANTIBODY)	TYPE III (IgG ANTIBODY)	*Type IV (T Cells)*			
				T_H1 CELLS	T_H2 CELLS	T_H17 CELLS	T CELLS
Antigen	Soluble antigen allergen	Cell- or matrix-associated antigen	Soluble antigen	Soluble antigen	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	FcεRI- or FcγRIII-dependent mast cell activation, with release of mediators/cytokines	$Fc\gamma R^+$ cells (phagocytes, NK cells), complement	$Fc\gamma R^+$ cells, complement	Macrophage activation	Eosinophil activation	Macrophage activation Neutrophil activation	Direct cytotoxicity
Examples	Systemic anaphylaxis, asthma, allergic rhinitis, urticaria, angioedema	Certain drug reactions and reactions to incompatible blood transfusions	Arthus reaction and other immune complex–mediated reactions (e.g., serum sickness, subacute bacterial endocarditis)	Contact dermatitis, tuberculin reaction	Chronic allergic inflammation (e.g., chronic asthma, chronic allergic rhinitis)	Contact dermatitis, atopic dermatitis, asthma, rheumatoid arthritis	Contact dermatitis (e.g., poison ivy), reactions to certain virus-infected cells, some instances of graft rejection

*Hypersensitivity reactions were classified into four types by Coombs and Gell (1963) and modified by Janeway and colleagues (2001).
FcγR = Fc receptor for immunoglobulin G; FcεR = Fc receptor for immunoglobulin E; NK = natural killer.

TABLE 46-2 CLASSIFICATION OF AUTOIMMUNE DISEASES ACCORDING TO MECHANISM OF TISSUE INJURY

HYPERSENSITIVITY REACTION	AUTOIMMUNE DISEASE	AUTOANTIGEN
TYPE II		
Antibody against cell-surface antigens	Autoimmune hemolytic anemia	Rh blood group antigens, I antigen
	Autoimmune thrombocytopenic purpura	Platelet integrin glycoprotein IIb:IIIa
Antibody against receptors	Graves' disease	Thyroid-stimulating hormone receptor (agonistic antibodies)
	Myasthenia gravis	Acetylcholine receptor (antagonistic antibodies)
Antibody against matrix antigens	Goodpasture's syndrome	Basement membrane collagen (α_3-chain of type IV collagen)
	Pemphigus vulgaris	Epidermal cadherin (desmoglein)
TYPE III		
Immune complex diseases	Mixed essential cryoglobulinemia	Rheumatoid factor IgG complexes (with or without hepatitis C antigens)
	Systemic lupus erythematosus	DNA, histones, ribosomes, binuclear proteins
TYPE IV		
T-cell-mediated diseases	Insulin-dependent diabetes mellitus	Pancreatic B-cell antigen
	Rheumatoid arthritis	Unknown synovial joint antigen
	Multiple sclerosis	Myelin basic protein, proteolipid protein

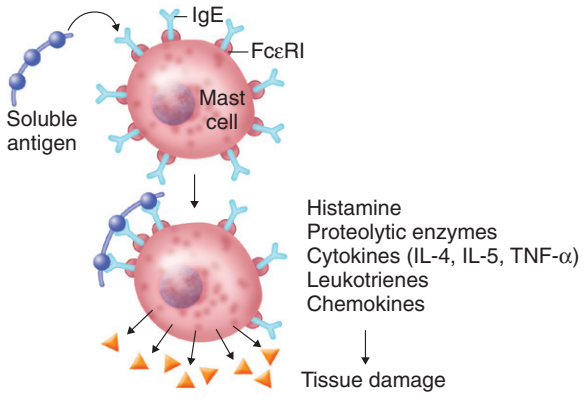

FIGURE 46-1. Type I hypersensitivity. Type I responses are mediated by immunoglobulin E (IgE), which induces mast cell activation. Cross-linking of the Fc receptor for IgE (FcεR) on mast cells, triggered by the interaction of multivalent antigen with antigen-specific IgE bound to FcεR, causes the release of preformed granules containing histamine and proteases. Cytokines, chemokines, and lipid mediators are synthesized after cell activation. IL = interleukin; TNF = tumor necrosis factor.

(asthma and allergic rhinitis); ingestion of antigens causes increased peristalsis and secretion (diarrhea and vomiting); and the presence of subcutaneous antigens initiates increased vascular permeability and swelling (urticaria and angioedema). Blood-borne antigens cause systemic mast cell activation, increased capillary permeability, hypotension, tissue swelling, and smooth muscle contraction—the characteristics of systemic anaphylaxis.

Type II Hypersensitivity Reactions

Type II hypersensitivity reactions (Fig. 46-2) are caused by chemical modification of cell surface or matrix-associated antigens that generates "foreign" epitopes to which the immune system is not tolerant. B cells respond to this antigenic challenge by producing IgG, which binds to these modified cells and renders them susceptible to destruction through complement activation, phagocytosis, and antibody-dependent cytotoxicity.

This phenomenon is seen clinically when drugs interact with blood constituents and alter their cellular antigens. Hemolytic anemia caused by immune-mediated destruction of erythrocytes (Chapter 163) and thrombocytopenia caused by destruction of platelets (Chapter 175), both type II hypersensitivity reactions, are adverse effects of certain drugs. Chemically reactive drug molecules bind covalently to the surface of red cells or platelets creating new epitopes that in a small subset of individuals are recognized as foreign antigens by the immune system and stimulate production of IgM and IgG antibodies reactive with the conjugate of drug and cell surface protein. Penicillin-specific IgG binds to penicillin-modified proteins on red blood cells and triggers activation of the complement cascade. Activation of complement components C1 through C3 results in covalent binding of C3b to the red cell membrane and renders circulating red cells susceptible to phagocytosis by FcγR and complement receptor–bearing macrophages in the spleen or liver. Activation of complement components C1 through C9 and formation of the membrane attack complex cause intravascular lysis of red cells. The factors that predispose only some people to drug-induced type II hypersensitivity reactions are unknown. Penicillin, quinidine, and methyldopa have been associated with hemolytic anemia and thrombocytopenia through this mechanism. Another example is heparin-induced

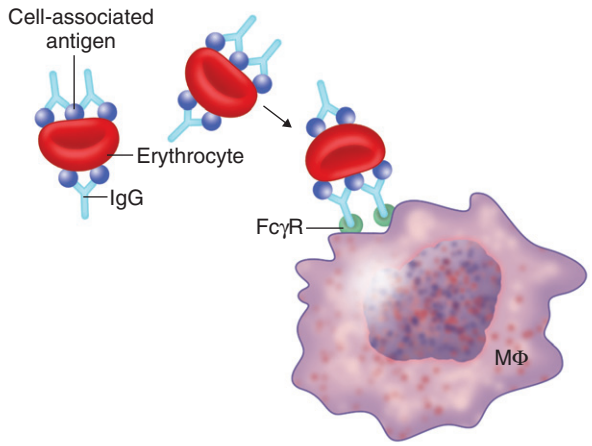

FIGURE 46-2. Type II hypersensitivity. Type II responses are mediated by immunoglobulin G (IgG) directed against cell surface or matrix antigens, which initiates effector responses through the Fc receptor for IgG (FcγR) and complement. The relative contributions of these pathways vary with the IgG subclass and the nature of the antigen. Only FcγR-mediated phagocytosis by macrophages (MΦ) is depicted in this figure. Activation of complement components would result in binding of C3b to the red blood cell membrane, rendering red blood cells susceptible to phagocytosis and leading to formation of the membrane attack complex and cell lysis.

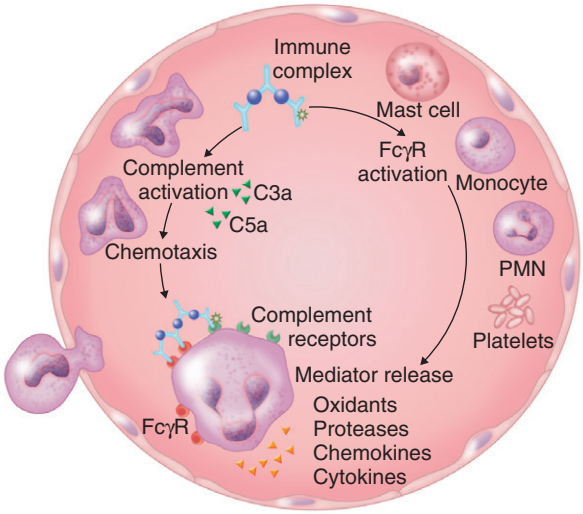

FIGURE 46-3. Type III hypersensitivity. Type III responses are mediated by immunoglobulin G (IgG) directed against soluble antigens. Localized deposition of immune complexes activates mast cells, monocytes, neutrophils, and platelets bearing the Fc receptor for IgG (FcγR), and initiates the complement cascade, all effectors of tissue damage. Generation of complement components C3a and C5a recruits and stimulates inflammatory cells and amplifies effector functions. PMN = polymorphonuclear leukocyte (also called *neutrophil*).

thrombocytopenia or thrombosis, a severe, life-threatening complication that occurs in 1 to 3% of patients exposed to heparin (Chapter 175). Interactions among heparin, human platelet factor 4, antibodies to the human platelet factor 4–heparin complex, platelet FcγRIIA, and splenic FcγRs (which remove opsonized platelets) are involved in the pathogenesis of this disease.

Autoantibodies directed at antigens on the cell surface or extracellular matrix cause tissue damage by mechanisms similar to type II hypersensitivity reactions. IgG or IgM antibodies against erythrocytes lead to cell destruction in autoimmune hemolytic anemia because opsonized cells (coated with IgG or IgM and complement) are removed from the circulation by phagocytes in the liver and spleen or are lysed by formation of the membrane attack complex. Platelet destruction in autoimmune thrombocytopenic purpura occurs through a similar process. Because nucleated cells express membrane-bound complement regulatory proteins, they are less sensitive to lysis through the membrane attack complex, but when coated with antibody, they become targets for phagocytosis or antibody-dependent cytotoxicity. This mechanism is responsible for autoimmune and alloimmune neutropenia (Chapter 170).

IgM and IgG antibodies recognizing antigens within tissue or binding to extracellular antigens cause local inflammatory damage through FcγR and complement mechanisms. Pemphigus vulgaris (Chapter 447) is a serious blistering disease that results from a loss of adhesion between keratinocytes caused by autoantibodies against the extracellular portions of desmoglein 3, an intercellular adhesion structure of epidermal keratinocytes. Another example of a type II hypersensitivity reaction is Goodpasture's disease (Chapter 123), in which antibodies against the α_3-chain of type IV collagen (the collagen in basement membranes) are deposited in glomerular and lung basement membrane. Tissue-bound autoantibodies activate monocytes, neutrophils, and basophils through FcγRs, initiating release of proteases, reactive oxidants, cytokines, and prostaglandins. Local activation of complement, particularly C5a, recruits and activates inflammatory cells and amplifies tissue injury. Neighboring cells are lysed by assembly of the membrane attack complex or by FcγR-initiated, antibody-dependent cytotoxicity.

Autoantibodies against cell surface receptors produce disease by stimulating or blocking receptor function. In myasthenia gravis (Chapter 430), autoantibodies against the acetylcholine receptors on skeletal muscle cells bind the receptor and induce its internalization and degradation in lysosomes, reducing the efficiency of neuromuscular transmission and causing progressive muscle weakness. In contrast, Graves' disease (Chapter 233) is characterized by autoantibodies that act as agonists. Autoantibodies to thyroid-stimulating hormone receptors bind the receptor, mimicking the natural ligand, inducing thyroid hormone overproduction, disrupting feedback regulation, and causing hyperthyroidism.

Type III Hypersensitivity Reactions

Type III hypersensitivity reactions (Fig. 46-3) are caused by tissue deposition of small soluble immune complexes that contain antigens and high-affinity IgG antibodies directed at these antigens. Localized deposition of immune complexes activates FcγR-bearing mast cells and phagocytes and initiates the complement cascade, all effectors of tissue damage.

Immune complexes are generated in all antibody responses. The formation and the fate of immune complexes depend on the biophysical and immunologic properties of the antigen and the antibody. These properties include the size, net charge, and valence of the antigen; the class and subclass of the antibody; the affinity of the antibody-antigen interaction; the net charge and concentration of antibody; the molar ratio of available antigen and antibody; and the ability of the immune complex to interact with the proteins of the complement system. The lattice size of the immune complex is influenced strongly by the physical size and valence of the antigen, the association constant of antibody for that antigen, the molar ratio of antigen and antibody, and the absolute concentrations of the reactants. Larger aggregates fix complement more efficiently, present a broader multivalent array of ligands for complement and FcγRs to bind, and are taken up more readily by mononuclear phagocytes in the liver and spleen and thereby removed from the circulation. Smaller immune complexes, which form in antigen excess—as occurs early in an immune response—circulate in the blood and are deposited in blood vessels, where they initiate inflammatory reactions and tissue damage through interactions with FcγRs and complement receptors.

Serum sickness is a systemic type III hypersensitivity reaction, historically described in patients injected with therapeutic horse antiserum for the treatment of bacterial infections. In general, serum sickness occurs after the injection of large quantities of a soluble antigen. Clinical features include chills, fever, rash, urticaria, arthritis, and glomerulonephritis. Disease manifestations become evident 7 to 10 days after exposure to the antigen, when antibodies are generated against the foreign protein and form immune complexes with these circulating antigens. Immune complexes are deposited in blood vessels, where they activate phagocytes and complement, producing widespread tissue injury and clinical symptoms. The effects are transient, however, and resolve after the antigen is cleared.

A syndrome similar to serum sickness occurs in chronic infections in which pathogens persist in the face of continued immune response. In subacute bacterial endocarditis (Chapter 76), antibody production continues but fails to eliminate the infecting microbes. As the pathogens multiply, generating new antigens, immune complexes form in the circulation and are deposited in small blood vessels, where they lead to inflammatory damage of skin, kidney, and nerve. Hepatitis B virus infection (Chapters 150 and 151) may be associated with immune complex deposition early in its course,

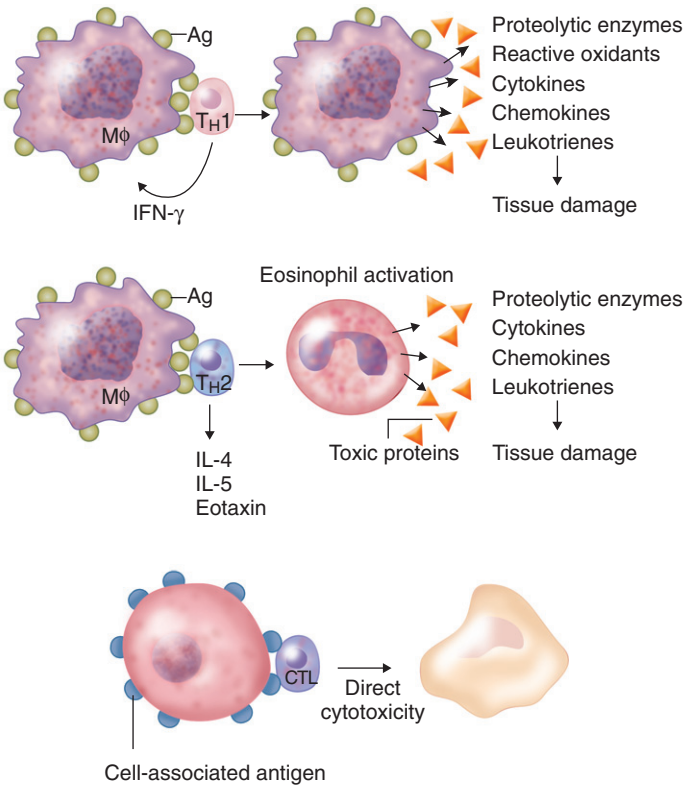

FIGURE 46-4. Type IV hypersensitivity. Type IV responses are mediated by T cells through three different pathways. In the first, type 1 helper T (T_H1) cells recognize soluble antigens (Ag) and release interferon-γ (IFN-γ) to activate effector cells, in this case macrophages (MΦ), and cause tissue injury. In T_H2-mediated responses, eosinophils predominate. T_H2 cells produce cytokines to recruit and activate eosinophils, leading to their degranulation and tissue injury lymphocytes (CTLs). In the third pathway, damage is caused directly by cytolytic T cells. IL = interleukin.

during a period of antigen excess, because antibody production in response to hepatitis B surface antigen is as yet relatively insufficient; some anicteric patients may present with acute arthritis. Mixed essential cryoglobulinemia, which may be associated with hepatitis C viral infection, is an immune complex–mediated vasculitis in which deposition of complexes containing IgG, IgM, and hepatitis C antigens causes inflammation in peripheral nerves, kidneys, and skin. Serum sickness also can develop in transplant recipients who are treated with mouse monoclonal antibodies specific for human T cells to prevent rejection, and in patients with myocardial infarction who are treated with the bacterial enzyme streptokinase to effect thrombolysis.

Systemic lupus erythematosus (Chapter 274), the prototypical immune complex–mediated autoimmune disease, is characterized by circulating IgG directed against common cellular constituents, typically DNA and DNA-binding proteins. Small immune complexes are deposited in skin, joints, and glomeruli and initiate local tissue damage.

Type IV Hypersensitivity Reactions

Type IV hypersensitivity reactions (Fig. 46-4), also known as *delayed-type hypersensitivity reactions,* are mediated by antigen-specific effector T cells. They are distinguished from other hypersensitivity reactions by the lag time from exposure to the antigen until the response is evident (1 to 3 days). Antigen is taken up, processed, and presented by macrophages or dendritic cells. Type 1 helper T (T_H1) effector cells that recognize the specific antigen (these are scarce and take time to arrive) are stimulated to release chemokines, which recruit macrophages to the site and release cytokines that mediate tissue injury. IFN-γ activates macrophages and enhances their release of inflammatory mediators, whereas TNF-α and TNF-β activate endothelial cells, enhance vascular permeability, and damage local tissue. The prototypical type IV hypersensitivity reaction is the tuberculin test, but similar reactions can occur after contact with sensitizing antigens (e.g., poison ivy, certain metals) and lead to epidermal reactions characterized by erythema, cellular infiltration, and vesicles. $CD8^+$ T cells also may mediate damage by direct toxicity.

In contrast to T_H1-mediated hypersensitivity reactions, in which the effectors are macrophages, eosinophils predominate in T_H2-mediated responses. T_H2 effector T cells are associated with tissue damage in chronic asthma (Chapter 87). T_H2 cells produce cytokines to recruit and activate eosinophils (IL-5 and eotaxin), leading to degranulation, further tissue injury, and chronic, irreversible airway damage.

T_H17 cells, members of the helper T-cell lineage, produce IL-17 family cytokines that regulate innate effectors and orchestrate local inflammation by inducing release of proinflammatory cytokines and chemokines, recruiting neutrophils, and enhancing T_H2 cytokine production to amplify allergic and autoimmune responses. T_H17 cells have been implicated in contact dermatitis, atopic dermatitis, asthma, and rheumatoid arthritis.

In some autoimmune diseases, effector T cells specifically recognize self-antigens to cause tissue damage, either by direct cytotoxicity or by inflammatory responses mediated by activated macrophages. In type 1 insulin-dependent diabetes mellitus, T cells mediate destruction of B cells of the pancreatic islets. IFN-γ–producing T cells specific for myelin basic proteins have been implicated in multiple sclerosis. Rheumatoid arthritis is another autoimmune disease caused, at least in part, by activated T_H1 cells.

MECHANISMS OF INFLAMMATION AND TISSUE REPAIR

GARY S. FIRESTEIN

THE INFLAMMATORY RESPONSE

Host defense mechanisms have evolved to recognize pathogens rapidly, render them harmless, and repair the damaged tissue. This complex and highly regulated sequence of events can also be triggered by environmental stimuli such as noxious mechanical and chemical agents. Under normal circumstances, tightly controlled responses protect against further injury and clear damaged tissue. In disease states, however, pathologic inflammation can lead to marked destruction of the extracellular matrix (ECM) and organ dysfunction.

Initiation of the Inflammatory Response

When normal tissue encounters a pathogen, resident cells are stimulated by engagement of pattern recognition receptors that activate an ancient arm of host defense known as *innate immunity*. In contrast to *adaptive immunity*, which provides exquisite antigen specificity, innate immune responses recognize common motifs on pathogens (Chapter 44). Additional cytoplasmic receptors can sense "danger" signals from a toxic environment or cellular stress, such as urate or adenosine triphosphate (ATP). Innate mechanisms are designed for rapid responses (minutes to hours) compared with the more leisurely adaptive system that can take days to weeks to develop. In addition to orchestrating early events that are critical to host defense, cells of the innate system like dendritic cells orchestrate the subsequent adaptive cascade through the generation of chemokines that organize lymphoid tissue and presentation of antigens to lymphocytes. Innate immunity provides intergenerational continuity in that the receptors are encoded in the germline and are passed unchanged to progeny to protect the species. In contrast, each individual must generate his or her own adaptive immune system through complex somatic mutations and gene rearrangements. This provides defense tailored for each member of the species; its complexity and beauty permit specificity but also provide opportunities for error such as responses against self-antigens in autoimmunity.

Pattern Recognition Receptors and Innate Immunity

The toll-like receptor (TLR) family of proteins, which bind molecular structures on microbial pathogens that normally are not found in mammalian

cells, are critical members of the innate immune system. Some are expressed on the cell surface, such as TLR2, which is activated primarily by bacterial peptidoglycan and lipoproteins, and TLR4, which is activated by lipopolysaccharide (LPS, or endotoxin). Others are expressed mainly on the inner leaflet of cytoplasmic vesicles, like TLR9, which is activated by unmethylated bacterial sequences that are enriched for CpG motifs, or TLR3 and TLR7, which are important for antiviral defense because they bind double-stranded and single-stranded viral RNA, respectively. In addition to exogenous molecules, some endogenous structures can bind to TLRs, including heat shock proteins and oxidized low-density lipoproteins (oxLDLs). The latter might be especially important in the pathogenesis of atherosclerosis, where LDL activates TLR4 within vascular plaques. Local endothelial cell– and macrophage-derived chemotactic factors can then recruit activated T cells into the atheroma.

Signaling by TLR2 and TLR4 progresses through adaptor proteins and often converges on a kinase known as MyD88, which orchestrates several downstream cascades. By directing the phosphorylation of IκB kinase-β (IKKβ), MyD88 activates nuclear factor-κB (NF-κB), a master switch for inflammatory genes. Translocation of NF-κB to the cell nucleus stimulates the production of cytokines (e.g., interleukin-6 [IL-6], IL-8, and tumor necrosis factor [TNF]), the machinery for prostaglandin release (e.g., cyclooxygenase 2 [COX2]), and genes that regulate the ECM (e.g., metalloproteinases). This rapid response is normally transient, although it can persist in pathogenic states. MyD88-independent pathways that stimulate innate immunity also exist. For instance, TLR3 stimulation by RNA viruses uses a separate pathway involving IKKβ and interferon regulating factor-3 (IRF-3). IRF-3, in combination with several other transcription factors, induces the expression of genes such as interferon-β (IFN-β) to establish an antiviral state.

These genes primarily offer protection against pathogens by initiating key defense mechanisms. However, these same pathways can create a hazardous milieu that is toxic to normal cells through the production of oxygen radicals, nitric oxide, and other reactive intermediaries. These molecules can damage DNA and harm bystander cells, or even lead to neoplasia (E-Table 47-1). For instance, long-standing inflammation in the colon, as in ulcerative colitis, is associated with adenocarcinoma. Increased COX2 expression as a result of NF-κB translocation is another mechanism that contributes to the development of tumors at inflammatory sites. An unanticipated finding is that NF-κB itself can also directly augment carcinogenesis by serving as a survival signal for damaged cells that would normally be deleted by apoptosis.

The TLR signal transduction mechanisms, initiated by broad categories of nonmammalian structures, integrate the environmental stimuli and generate a broadly antipathogenic response. Fine-tuning of host defenses against unique pathogen structures to provide long-lived immunity requires the slower, more precise adaptive immune system. Although it is more cumbersome and primitive, innate immunity provides signals that activate adaptive responses. For instance, TLRs can stimulate dendritic cells (Chapter 44), which have internalized and processed antigen, to migrate from peripheral tissues to central lymphoid organs. The dendritic cells can also produce cytokines and, after maturation, present antigens to T cells in the context of class II major histocompatibility molecules and surface costimulatory proteins. The activated T cells can then migrate to the tissue to enhance and amplify the host response. T cells also provide help to B cells, thereby stimulating antibody production and activating other components of innate immunity (e.g., the complement system).

The Inflammasome and Innate Immune Responses

Receptors that can recognize "danger" signals and potential pathogens are present in the cell cytoplasm. The inflammasome is among the best characterized systems and includes the 22-family-member human Nod-like receptor (NLR) family of cytoplasmic proteins. The activated NLR proteins recruit additional proteins to form a complex with caspase-1 and adaptor molecule apoptosis-associated specklike protein (ASC). Activation of caspase-1 is one of the critical functions of inflammasomes, with resultant cleavage and activation of IL-1, IL-18, and IL-33.

Disorders of the inflammasome can lead to autoinflammatory diseases. The prototypic syndromes known as familial cold autoinflammatory disease, Muckle-Wells disease, and neonatal-onset multisystem inflammatory disease (NOMID) are due to nonconserved mutations in the NLR gene that encodes cryopyrin (also known as NALP3). These three rare diseases are characterized by abnormal inflammasome activation with aberrant release of processed IL-1β. The clinical manifestations, including fever, rash, hearing impairment, and arthritis, depend on the specific amino acid substitution as well as other less well-defined genetic influences. The critical role of IL-1 has been proved by studies using treatment with IL-1 inhibitors, which prevent flares and, in some cases, appear to reverse end-organ disease. The inflammasome also appears to play a key role in other more common diseases, such as gout, in which urate crystals can activate the inflammasome. IL-1 inhibitors also appear to be effective in some patients, although long-term controlled studies are needed.

Immune Complexes and Complement

The complement system (Chapter 49) is another ancient defense mechanism that links innate immunity and the humoral arm of adaptive immunity. Both the classical complement pathway, activated by immunoglobulin G (IgG)– and IgM-containing immune complexes, and the alternative pathway, activated by bacterial products, converge at the third component of complement, C3, with proteolytic release of fragments that amplify the inflammatory response and mediate tissue injury. The anaphylotoxins C3a and C5a directly increase vascular permeability and contraction of smooth muscle. C3a and C3a desArg also induce TNF and IL-1β production by peripheral blood mononuclear cells. C5a induces mast cell release of histamine, thereby indirectly mediating increased vascular permeability. C5a also activates leukocytes and enhances their chemotaxis, adhesion, and degranulation, with release of proteases and toxic metabolites. C5b attaches to the surface of cells and microorganisms and is the first component in the assembly of the C5b-9 membrane attack complex.

Individuals with abnormalities of the early complement components, especially C1q, C2, and C4, usually have a minimally increased incidence of infection but demonstrate an enhanced risk of developing autoimmune diseases such as systemic lupus erythematosus (SLE) (Chapter 274). The mechanism of increased disease susceptibility is probably related to inefficient clearance of immune complexes. Enhanced activation and consumption of complement proteins can also occur in SLE accompanied by low plasma C3 and C4 levels, especially in association with disease exacerbations. C3 or C5 deficiency causes increased susceptibility to bacterial infections, whereas defects in the late components that form the membrane attack complex result in an increased incidence of *Neisseria* sp bacteremia.

Environmental Stress and Tissue Damage

Tissue injury due to direct trauma or noxious stimulus also initiates an inflammatory response and is associated with microvascular damage, extravasation of leukocytes through vascular walls, and leakage of plasma and proteins into the tissue. As noted previously, the inflammasome acts as a sensor that can initiate this program in some cases. In other cases, such as ischemia, acid-sensitive ion channels on the cell surface can detect the environmental stress due to a decrease in tissue pH. Thrombus formation at the site of vascular damage begins the inflammatory cascade through the release of vasoactive amines (e.g., serotonin), release of lysosomal proteases, and formation of eicosanoid products. The platelets can also later regulate healing with release of growth factors such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β).

Second Wave of the Inflammatory Response

Activation of innate immunity quickly leads to the robust influx of inflammatory cells. Resident cells, such as vascular endothelial cells, mast cells, dendritic cells, and interstitial fibroblasts, respond by releasing soluble mediators, including eicosanoids and pro-inflammatory cytokines (E-Table 47-2). These mediators amplify the inflammatory response and recruit additional leukocytes. Locally stimulated cells, along with the newly arrived inflammatory cells, release toxic reactive intermediates of nitrogen and oxygen as well as a myriad of proteases, principally matrix metalloproteinases (MMPs), serine proteases, and cysteine proteases. These molecules are designed to help destroy infectious agents and remove damaged cells, thus clearing the injured site for tissue repair. Prolonged stimulation of acute inflammatory mechanisms can cause severe tissue destruction. However, in most situations, the normal physiologic response is an exquisitely coordinated program that uses proteolytic enzymes to remodel the ECM and promote a supportive environment for wound healing rather than tissue damage.

Cellular Response

Inflammatory cell infiltration at the site of initial tissue damage typically progresses in an orderly fashion. The process begins with release of chemokines and soluble mediators from resident cells, including interstitial fibroblasts,

mast cells, and vascular endothelial cells. Signaling from these events alters the local adhesion molecule profile and creates a chemotactic gradient that recruits cells from the blood stream. Mast cells, in particular, act as sentinels and can degranulate within seconds to release vasoactive amines. In most acute responses, polymorphonuclear leukocytes (PMNs) are the first inflammatory cells to extravasate from the circulation and arrive at the site of injury, followed later by mononuclear cells under the influence of separate signals.

Most tissue fibroblasts and vascular endothelial cells are quiescent before migration of PMNs into the tissue. However, these resident cells can be triggered to proliferate and migrate toward the site of injury as well as to synthesize cytokines, proteases, and ECM components. Growth factors are released, such as basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF), stimulating new blood vessel formation. Together with granulocyte-macrophage colony-stimulating factor (GM-CSF), these locally released growth factors contribute to cellular proliferation and amplification of the inflammatory response and also induce maturation of dendritic cells that process antigens. In addition, fibroblasts and endothelial cells secrete new ECM proteins, MMPs, and other ECM-digesting enzymes. The balance of protease and ECM production varies as tissue is remodeled during the course of inflammation. Initially, the response favors proteolytic activity to clear damaged infrastructure. This is followed by a shift to increased production of new ECM to allow tissue repair and wound healing.

Increased vascular permeability, caused by disruption of endothelial cell tight junctions, allows blood-borne proteins such as fibrinogen, fibronectin, and vitronectin to extravasate into the perivascular ECM. Interaction with preexisting ECM allows the assembly of new ligands for a subset of adhesion molecules (e.g., integrins $\alpha5\beta1$ and $\alpha v\beta3$). This increased vascular permeability and change in the profiles of adhesion molecules and ligands, in conjunction with release of chemoattractant molecules, lead to the recruitment of leukocytes to sites of inflammation. Some of the chemokines involved are IL-8 (for neutrophils), macrophage chemoattractant protein-1 (MCP-1) for monocytes, RANTES (regulated on activation, T-cell expressed and secreted) for monocytes and eosinophils, and IL-16 (for $CD4^+$ T cells). In addition, chemokines recruit specific subsets of cells by binding to chemokine receptors.

The precise combination of chemokines and vascular adhesion molecules present in an inflammatory lesion determines the specificity of time and event for the recruitment of subsets of inflammatory cells. Ligation of integrins on leukocytes also prolongs cell survival once they have moved into the tissue, by preventing apoptosis. The central role of certain specific adhesion molecule-ligand pairs has been confirmed in human diseases. For instance, $\alpha4\beta1$ plays a key role in the recruitment of lymphocytes to the central nervous system in multiple sclerosis, and blocking this interaction suppresses disease activity (Chapter 419). Eosinophils also use the same adhesion receptors to migrate into the lung in allergen-induced asthma (Chapter 87).

Increased expression of intracellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), as well as increased chemokine expression, is also evident in other cell types, such as the airway epithelium after allergen challenge in asthma. Rapid and transient influx of neutrophils occurs in allergic airway disease, along with activation of the local T cells and mast cells. These neutrophils produce lipid mediators, reactive oxygen intermediates, and proteases such as elastase, which may contribute to airflow obstruction, epithelial damage, and remodeling. Neutrophil elastase, together with chemokines released by both recruited and allergen-activated T cells and mast cells, serves to recruit eosinophils.

Soluble Mediators

Pro-inflammatory Cytokines

Pro-inflammatory cytokines, often derived from macrophages and fibroblasts, are mediators that activate the immune system. The pro-inflammatory members of the IL-1 family (IL-α, IL-1β, IL-18, and IL-33) and TNF have pleiotropic activities and can enhance adhesion molecule expression on endothelial cells, induce proliferation of endogenous cells, and stimulate antigen presentation. IL-1 and TNF also increase expression of matrix-degrading enzymes, such as collagenase and stromelysin. In addition, they stimulate synthesis of other inflammatory mediators such as prostaglandin E_2 (PGE_2) from fibroblasts. Inhibitors of TNF are effective therapeutic agents in inflammatory diseases such as psoriasis, rheumatoid arthritis, and inflammatory bowel disease, and IL-1 inhibitors are beneficial in genetic diseases such as Muckle-Wells syndrome and familial cold autoinflammatory syndrome.

IL-1 and TNF comprise only a small fraction of the acute cytokine response. Many other factors also participate, including IL-6 and its related cytokines (IL-11, osteopontin, and leukemia inhibitory factor), which can both induce acute phase reactants and bias an immune response toward a helper T type 1 (T_H1) or T_H2 phenotype (Chapter 46). GM-CSF can regulate dendritic cell maturation, increase expression of human leukocyte antigen (HLA-DR) on these cells, and enhance antigen presentation. The T_H1 lymphokine IFN-γ, although often considered part of the secondary wave that ensues after T-cell activation, can also induce expression of HLA-DR, increase expression of endothelial cell adhesion molecules, and inhibit collagen production. IL-1, IL-6, and IL-23 coordinate differentiation toward Th17 cells, a phenotype that is thought to play a major role in inflammation and autoimmunity owing to the production of IL-17 family members (IL-17A through F). Of these, IL-17A and perhaps IL-17F are especially important because they can synergize with IL-1 and TNF. The growth factor TGF-β biases cells toward the regulatory T cell (Treg) phenotype, which can suppress antigen-specific responses of other T cells (see later).

Cytokines play a key role in the establishment and perpetuation of inflammatory diseases. In rheumatoid arthritis (Chapter 272), autocrine and paracrine cytokine networks play a critical role in the perpetuation of inflammation. Effects of IL-1 and TNF are often central to continued synovitis, and there is increasing evidence that IL-15 participates by enhancing TNF production. IL-17A contributes to synoviocyte activation, and IL-18 can trigger T-cell differentiation toward a T_H1 phenotype. Factors such as MCP-1 recruit and activate macrophages into atheromas containing oxLDLs and foam cells. In allergic asthma (Chapter 87), IL-13 is emerging as a central inflammatory cytokine. IL-13 functions through binding to cell surface IL-4 receptors, and IL-4R–deficient mice are relatively resistant to the development of asthma. An IL-23 inhibitor, ustekinemab, has shown dramatic efficacy in psoriasis, indicating a major role for this pathway in inflammatory skin disease.

Eicosanoids

In addition to cytokines and immune complexes, local inflammatory responses lead to the release of eicosanoids, which are lipid-derived molecules. Because lipids are present in the cell membrane, they are readily available substrates for the synthesis of mediators. These molecules are functional immediately adjacent to sites of synthesis, and their half-lives range from seconds to minutes. Eicosanoids are not stored but are produced de novo from membrane lipids when cell activation by mechanical trauma, cytokines, growth factors, or other stimuli leads to release of arachidonic acid. Cytosolic phospholipase A_2 ($cPLA_2$) is the key enzyme in eicosanoid production. Cell-specific and agonist-dependent events coordinate the translocation of $cPLA_2$ to the nuclear envelope, endoplasmic reticulum, and Golgi apparatus, where interaction with cyclooxygenase (COX) (in the case of prostaglandin synthesis) or 5-lipoxygenase (in the case of leukotriene synthesis) can occur.

Prostaglandins

Prostanoids are produced when arachidonic acid is released from the plasma membrane of injured cells by phospholipases and metabolized by cyclooxygenases and specific isomerases (Chapter 36). These molecules act both at peripheral sensory neurons and at central sites within the spinal cord and brain to evoke pain and hyperalgesia. Their production is increased in most acute inflammatory conditions, including arthritis and inflammatory bowel disease. In response to exogenous and endogenous pyrogens, PGE_2 derived from COX2 mediates a central febrile response. In addition, prostaglandins synergize with bradykinin and histamine to enhance vascular permeability and edema. The levels of prostaglandins are usually very low in normal tissues and increase rapidly with acute inflammation, well before leukocyte recruitment. COX2 induction with inflammatory stimuli most likely accounts for the high levels of prostanoids in chronic inflammation.

COX2 also plays a key role in platelet-endothelial cell interactions by increasing the production of prostacyclin (PGI_2) in endothelial cells (Chapter 36). Increased risk of myocardial infarction associated with the use of selective COX2 inhibitors might be related to unopposed production of thromboxane A_2 by COX1 in platelets. Prostacyclin production also protects against atherosclerosis in female mice, and COX2 blockade abrogates this beneficial effect. Thus, COX inhibitors can potentially increase thrombotic events.

Leukotrienes

In addition to prostaglandins, a distinct set of enzymes direct arachidonic acid metabolites toward the synthesis of leukotrienes (Chapter 87). Their relative importance depends on the specific target organ of an inflammatory response. For instance, leukotriene receptor antagonists have demonstrated

efficacy in asthma, whereas similar approaches have been less impressive in rheumatoid arthritis. Unlike prostaglandins, leukotrienes are primarily produced by inflammatory cells such as neutrophils, macrophages, and mast cells. 5-Lipoxygenase is the key enzyme in this cascade, transforming released arachidonic acid to the epoxide leukotriene A_4 (LTA_4) in concert with 5-lipoxygenase-activating protein (FLAP). LTA_4 can be hydrolyzed by cytosolic LTA_4 hydrolase to LTB_4, a potent neutrophil chemoattractant and stimulator of leukocyte adhesion to endothelial cells. LTA_4 can also conjugate with glutathione to form LTC_4 by LTC_4 synthase at the nuclear envelope. LTC_4 migrates out of the cell, using transporters such as the multidrug resistance–associated protein, and can be metabolized extracellularly to LTD_4 and LTE_4. These three cysteinyl leukotrienes comprise the "slow-reacting substance of anaphylaxis" for their slow and sustained smooth muscle–contracting abilities. They promote plasma leakage from postcapillary venules, upregulation of expression of cell surface adhesion molecules, and bronchoconstriction.

Histamine

Histamine is a vasoactive amine produced by basophils and mast cells that markedly increases capillary leakage. In basophils, histamine is released in response to bacterial formylmethionyl-leucyl-phenylalanine (f-MLP) sequences, complement fragments C3a and C5a, and IgE. The resultant edema can be readily observed clinically in urticaria (Chapters 260 and 448) and allergic rhinitis (Chapter 259). Despite the production of histamine in asthma and in acute synovitis, histamine blockers have minimal therapeutic effect in these conditions. The stimulus for release of histamine from mast cell granules is the same as in basophils, except for the absence of f-MLP receptors in this cell type. Histamine can also synergize with locally produced LTB_4 and LTC_4. In addition, histamine enhances leukocyte rolling and firm adhesion, and induces gaps in the endothelial cell lining, enhancing leukocyte extravasation.

Kinins

Kinins induce vasodilation, edema, and smooth muscle contraction, as well as pain and hyperalgesia, through stimulation of C fibers. They are formed from high- and low-molecular-weight kininogens by the action of serine protease kallikreins in plasma and peripheral tissues. The primary products of kininogen digestion are bradykinin and lysyl-bradykinin. These products have high affinity for the B2 receptor, which is widely expressed and is responsible for the most common effects of kinins. The peptides desArg-BK and Lys-desArg-BK are generated by carboxypeptidases and bind the kinin B1 receptor subtype, which is not expressed in normal tissues but is rapidly upregulated by TLR ligands and cytokines. The kinin B2 receptor is internalized rapidly and desensitized, whereas the B1 receptor remains highly responsive. Kinin actions are associated with the secondary production of other mediators of inflammation, including nitric oxide, mast cell–derived products, and the pro-inflammatory cytokines IL-6 and IL-8. In addition, kinins can increase IL-1 production through initial stimulation of TNF and can increase prostanoid production through activation of phospholipase A_2 and release of arachidonic acid.

Mechanisms of Tissue Damage in Inflammation

Reactive Oxygen and Nitrogen

Macrophages, neutrophils, and other phagocytic cells can generate large amounts of toxic reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates (RNIs) that can directly kill pathogens. ROIs and RNIs also serve as critical signal transduction molecules that regulate expression of inflammatory genes.

These molecules can have deleterious effects on normal tissue by damaging DNA, oxidizing membrane lipids, and nitrosylating proteins. Release of reactive intermediates can be initiated by microbial products such as LPS and lipoproteins, by cytokines such as IFN-γ and IL-8, and by engagement of Fc receptors by IgG. These events cause translocation of several cytosolic proteins, including Rac2 and Rho-family guanosine triphosphatase (GTPase) to the membrane-bound complex carrying cytochrome *c*, with subsequent activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. The reaction catalyzed by NADPH oxidase leads to superoxide production, which, in turn, increases hydrogen peroxide, hydroxyl radicals and anions, hypochlorous acid, and chloramines.

In some cases, ROIs can contribute directly to the initiation of chronic disease. Lipid oxidation produces aldehydes that substitute lysine residues in apolipoprotein B-100. This altered moiety either binds to TLR2 to induce cytokine production or is internalized by macrophages, leading to the production of foam cells and fatty streaks, the primary lesions of atherosclerosis (Chapter 70). Subsequently, altered epitopes in damaged host proteins can be presented to T cells to initiate an adaptive immune response that amplifies the inflammatory vascular lesion.

Nitric oxide synthases (NOS) convert L-arginine and molecular oxygen to L-citrulline and nitric oxide (NO). There are three known isoforms of NOS: neuronal NOS (ncNOS or NOS1) and endothelial cell NOS (ecNOS or NOS3) are both constitutively expressed, whereas macrophage NOS (macNOS, iNOS, or NOS2) is induced by inflammatory cytokines such as TNF-α and IFN-γ, as well as by products of viruses, bacteria, protozoa, and fungi and by low oxygen tension and low environmental pH.

Together with prostaglandins, the production of NO by NOS2 and ROIs by NADPH oxidase is a key mechanism by which macrophages paradoxically impair T-cell proliferation. This might control inflammatory processes or delete autoreactive T cells and partially accounts for the immunosuppression observed in certain infections and malignancies.

Proteases

Production of enzymes that degrade the ECM represents a key mechanism of tissue turnover in inflammation. Reconfiguring of the matrix remodels damaged tissue, releases matrix-bound growth factors and cytokines, prepares the tissue for the ingrowth of new blood vessels, and alters the local milieu to permit adherence and retention of newly recruited cells.

The MMPs are a family of more than 20 extracellular endopeptidases that participate in degradation and remodeling of the ECM matrix (Table 47-1). They are produced as pro-enzymes and require limited proteolysis or partial denaturation to expose the catalytic site. Their name is derived from their dependence on metal ions (zinc/metzincin superfamily) for activity and from their potent ability to degrade structural ECM proteins. MMPs can also cleave cell surface molecules and other pericellular nonmatrix proteins, thereby regulating cell behavior. For instance, MMPs can alter cell growth by digesting matrix proteins associated with growth factors. FGF and TGF-β

TABLE 47-1 COMMON MATRIX METALLOPROTEINASES (MMPS) AND THEIR SUBSTRATES

have high affinities for matrix molecules that serve as depots for storage of these cytokines in their activation state. Matrix proteolysis releases some growth factors and can make them available to cell surface receptors. In addition, MMPs can directly cleave and activate growth factors. MMPs affect cell migration by altering cell-matrix or cell-cell receptor sites. For instance, the adhesion molecule β4 integrin is cleaved by MMP-7. MMP-3 and MMP-7 digest E-cadherin and not only disrupt endothelial cell junctions but also stimulate cell migration.

Degradation of the ECM is usually initiated by collagenases, which cleave native collagen. Denatured collagen is then recognized and further degraded by gelatinases and stromelysins. Unlike the collagenases, stromelysins demonstrate broad substrate specificity and act on many ECM proteins, such as proteoglycan, fibronectin, laminin, and many cartilage proteins. Stromelysins can also amplify the remodeling process by activating collagenase through limited proteolysis. MMP gene expression can be induced by many proinflammatory cytokines, including TNF, IL-1, IL-17, and IL-18, through MAP kinase signal transduction pathways.

Several other classes of proteases remodel the matrix, including serine proteases and cysteine proteases. High levels of active serine proteases, such as trypsin, chymotrypsin, and elastase, are released by infiltrating PMNs at sites of inflammation and can directly digest the ECM or activate the proenzyme forms of secreted MMPs. The ADAM (a disintegrin and metalloproteinase) family can cleave the extracellular domain of cytokine receptors. These ECM proteases include two members of the aggrecanase family. One of the aggrecanases (aggrecanase 2, or ADAMTS5) has been implicated in osteoarthritis because mice deficient in this enzyme have decreased cartilage destruction in models of osteoarthritis.

Tissue Repair and Resolution of Inflammation

Inflammation is a normal physiologic response, but it can cause serious host injury if it is allowed to persist. Hence, additional mechanisms are required to reestablish homeostasis once this response is initiated. Suppression of acute inflammation by removal or deactivation of mediators and effector cells permits the host to repair damaged tissues through elaboration of appropriate growth factors and cytokines (Fig. 47-1). As in the initial generation of an inflammatory response, components of resolution include a cellular response (apoptosis and necrosis), formation of soluble mediators (such as anti-inflammatory cytokines and antioxidants), and production of direct effectors (such as protease inhibitors).

Deletion of Inflammatory Cells

Cells can be removed from an inflammatory site by several mechanisms. First, the influx of cells can be decreased by suppressing chemotactic factor production and vascular adhesion molecule expression. Second, cells, especially lymphocytes, can be released from the tissue and return to the circulation through lymphatics. Third, stressed cells can undergo necrosis with the release of their contents into the local environment. Perhaps the most critical mechanism for clearing cells from an inflammatory site is programmed cell death, or apoptosis.

Apoptosis is a highly regulated process in eukaryotic cells that leads to cell death and marks the surface membrane for rapid removal by phagocytes. This clearance process does not elicit an inflammatory response, in contrast to cell death by necrosis. PMN phagocytes have a very short half-life in the tissue, and the persistence or release of their contents into the microenvironment after death can be deleterious. In some pathologic conditions, such as leukocytoclastic vasculitis (Chapter 278), abundant neutrophil apoptosis is readily apparent on histopathologic examination; in fact, it is one of the pathologic criteria for this diagnosis. Other cells, including T lymphocytes, undergo postactivation apoptosis to prevent their overwhelming of host responses. Defective apoptosis or even persistence of apoptotic cells that escape clearance may contribute to chronic inflammatory and autoimmune diseases. For instance, loss of tolerance to self-antigens might participate in autoimmune responses in SLE.

Commitment of a cell to apoptosis can be initiated by a number of factors, including the ROIs in the cellular microenvironment as well as signaling through several death receptor pathways (e.g., FasL/Fas and TNF-related apoptosis-inducing ligand [TRAIL]). The former can damage DNA, which is a common byproduct of the genotoxic environment created by inflammation. If DNA damage is excessive, repair by tightly regulated mismatch repair mechanisms is terminated, and programmed cell death begins. The burden of mutations induced by ROIs or RNIs in chronic inflammation can potentially accumulate over time and eventually lead to amino acid substitutions in key regulatory proteins. Ultimately, as has been observed in ulcerative colitis, neoplastic disease can ensue.

Removal of apoptotic bodies, or the remnants of packaged apoptotic cells, is rapid and can be accomplished by macrophages, fibroblasts, epithelial and endothelial cells, muscle cells, and dendritic cells. The surface receptors used in recognition and engulfment of apoptotic cells include integrins (e.g., αvβ3), lectins, scavenger receptors, adenosine triphosphate (ATP)-binding cassette transporter 1, LPS receptor, CD14, and complement receptors CR3 and CR4. However, some of these membrane molecules can be used in both pro-inflammatory and apoptotic pathways, the divergence of which may be based on differing ligands and accessory molecules. Apoptotic cells display a series of membrane-associated molecular patterns that interact with receptors on phagocytes. The details of interactions between apoptotic cells and phagocytes are only partially understood. A general feature of apoptotic cells is loss of phospholipid asymmetry, with external presentation of phosphatidylserine. Externalized phosphatidylserine may be sufficient to trigger phagocytosis, but other apoptotic cell surface structures exist.

Although some inflammatory and immune cells are being deleted, other cell lineages expand during the resolution phase. Mesenchymal cells, especially fibroblasts, proliferate and produce new matrix that can contract to form

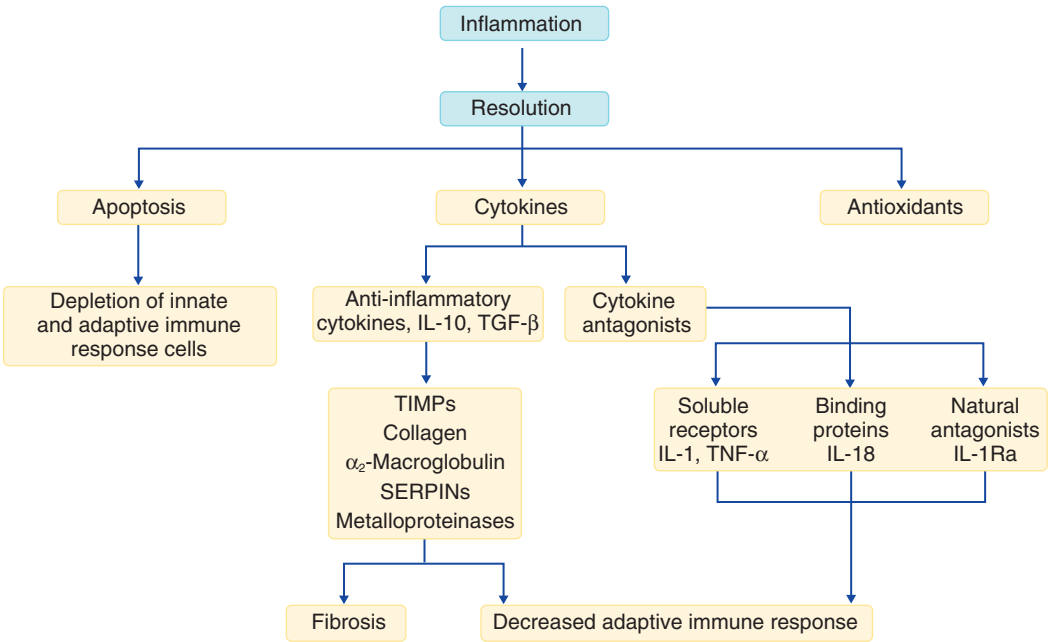

FIGURE 47-1. Anti-inflammatory mechanisms that resolve inflammation and lead to repair of the extracellular matrix. IL = interleukin; SERPINs = serine protease inhibitors; TGF = transforming growth factor; TIMPs = tissue inhibitor of metalloproteinases; TNF = tumor necrosis factor.

a fibrotic scar. Locally produced growth factors such as PDGF and TGF-β induce DNA synthesis of these stromal cells. In addition, mesenchymal stem cells that either reside in the tissue or migrate from the peripheral blood can differentiate into the appropriate organ-specific lineage. The pluripotential cells, in the presence of the appropriate milieu, can become adipocytes, chondrocytes, bone cells, or other terminally differentiated stromal cells.

Soluble Mediators

Anti-inflammatory Cytokines

A variety of anti-inflammatory cytokines are released by resident and infiltrating cells. TGF-β and IL-10 are examples that are produced by macrophages, interstitial fibroblasts, or T cells. Some T-cell cytokines, including IL-4, IL-10, and IL-13, suppress the expression of MMP by cells stimulated by IL-1 or TNF. In addition to increasing fibroblast proliferation, TGF-β suppresses collagenase production, increases collagen deposition, and decreases MMP activity by inducing production of the tissue inhibitors of metalloproteinases (TIMPs). The repair phase is abnormal in diseases in which tissue fibrosis represents a major pathologic manifestation. For example, scleroderma (Chapter 275) is marked by diffuse fibrosis and is accompanied by high levels of TGF-β and increased production of ECM.

Cytokine decoy receptors can also downregulate the inflammatory response. Receptors can also be shed from the cell surface after proteolytic cleavage and can absorb cytokines, thereby preventing them from ligating functional receptors on cell membranes. These cytokine inhibitors can be released as a coordinated attempt to prevent unregulated inflammation, as in septic shock (Chapter 108), in which endotoxin induces production of soluble receptors after initial massive production of TNF and IL-1. Other types of cytokine-binding proteins are also produced as counter-regulatory mechanisms, including IL-18-binding protein (IL-18BP), which is an Ig superfamily-related receptor that captures IL-18. In bone remodeling (Chapter 251), interactions of receptor activator of NF-κB (RANK) with RANK ligand are required for osteoclast-mediated resorption. The competitive antagonist osteoprotegerin is a member of the TNF receptor family that binds to RANK ligand and inhibits osteoclast activation.

The need for tight control of the pro-inflammatory cytokine IL-1 is demonstrated by the existence of two separate mechanisms. An IL-1 decoy receptor, known as the type II IL-1R, has both cell membrane and soluble forms that neutralize IL-1 activity. In addition, a natural IL-1 antagonist, IL-1Ra, can bind to functional IL-1 receptors and compete with IL-1α or IL-1β. However, IL-1Ra does not transduce a signal to the cell and blocks the biologic functions of ambient IL-1. The balance of IL-1 and IL-1Ra production depends on many influences. For instance, monocytes produce more IL-1, whereas mature macrophages produce IL-1Ra.

Prostanoids and Cyclooxygenase

COX2 induced by pro-inflammatory mediators appears early and can contribute to inflammatory responses. However, COX2 expression late in the process has led to speculation that it also functions in the resolution of inflammation. This regulation might occur through formation of the cyclopentenone prostaglandins (CyPG). The prostanoids can serve as ligands for peroxisome proliferator-activated receptors (PPARs) (Chapter 213). There are three main classes of PPAR receptors—PPARα, PPARβ/δ, and PPARγ—all of which bind to DNA as heterodimers in association with the retinoid X receptor. Activation of PPARγ by CyPG is associated with the suppression of activator protein 1 (AP-1) and signal transducer and activator of transcription (STAT) transcriptional pathways in macrophages. A variety of natural and synthetic PPAR agonists have demonstrated efficacy in models of ischemia-reperfusion injury, arthritis, and inflammatory airway disease.

Inhibitors of Direct Effectors

Antioxidants

Antioxidant enzymes that can inactivate the toxic intermediates and protect normal tissues include catalase and superoxide dismutase. Catalase is a peroxisomal enzyme that catalyzes the conversion of hydrogen peroxide to water and oxygen. Superoxide dismutases (SOD) catalyze the dismutation of superoxide to hydrogen peroxide, which is then removed by catalase or glutathione peroxidase. Glutathione peroxidases and glutathione reductase are additional mechanisms for maintaining redox balance and removal of toxic metabolites. Insufficient production of intracellular antioxidants such as glutathione can suppress lymphocyte responses and could account for defective T-cell receptor signaling and blunted immunity in T cells derived from rheumatoid arthritis synovium (Chapter 272).

Interactions of free radicals with surrounding molecules can generate secondary radical species in a self-propagating chain reaction. Chain-breaking antioxidants are small molecules that can receive or donate an electron and thereby form a stable byproduct with a radical. These antioxidant molecules are categorized as either aqueous phase (vitamin C, albumin, reduced glutathione) or lipid phase (vitamin E, ubiquinol-10, carotenoids, and flavonoids). In addition, transition metal-binding proteins (ceruloplasmin, ferritin, transferrin, and lactoferrin) can serve as antioxidants by sequestering cationic iron and copper and thereby inhibiting the propagation of hydroxyl radicals.

Protease Inhibitors

Protease inhibitors regulate the function of endogenous proteases and reduce the likelihood of collateral damage to tissues. These proteins form two functional classes, active site inhibitors and α_2-macroglobulin (α2M). The latter class of protease inhibitors acts by covalently linking the protease to the α2M chain and thereby blocking access to substrates. α2M binds to all classes of proteases and, after forming a covalent bond, conveys them to cells through receptor-mediated endocytosis with subsequent enzymatic inactivation. The family of inhibitors of serine proteases (SERPINs) are the most abundant members of the former class of protease inhibitors and play a major role in regulation of blood clot resolution and inflammation, as indicated by many of their names: antithrombin III, plasminogen activator inhibitors 1 and 2, α_2-antiplasmin, α_1-antitrypsin, and kallistatin.

The tissue inhibitor of metalloproteinases (TIMP) family blocks the function of most MMPs. The TIMPs bind to activated MMPs and irreversibly block their catalytic sites. Examples of disease states with an unfavorable balance between TIMPs and MMPs include loss of cartilage in arthritis and regulation of tumor metastasis. TIMP-MMP imbalance in destructive forms of arthritis appears be caused by the limited production capacity for protease inhibitors, which is overwhelmed by the prodigious expression of MMPs. Whereas IL-1 and TNF-α induce MMPs, IL-6, TGF-β, and several other growth factors suppress production of MMPs and increase levels TIMPs. Therefore, the cytokine profile has a pivotal influence on the status of remodeling. When pro-inflammatory cytokines predominate, the balance favors matrix destruction; in the presence of pro-inflammatory cytokine inhibitors and growth factors, matrix protein production increases, and MMPs are inhibited by TIMPs.

TRANSPLANTATION IMMUNOLOGY

MEGAN SYKES

DEFINITION

Clinical transplantation encompasses the transplantation of organs and islets of Langerhans, in which it is necessary to overcome the host-versus-graft (HVG) immune response to avoid rejection, as well as hematopoietic cell transplantation (HCT; Chapter 181), in which not only the HVG but also the graft-versus-host (GVH) immune response must be contended with. Because preparations of marrow or mobilized peripheral blood stem cells contain mature T cells, their administration to conditioned, and consequently immunoincompetent, recipients is associated with the risk of GVH disease. Organs transplanted include the cornea, kidney, liver, heart, lung,

small intestine, and pancreas, and even the hand and face. The list of transplanted allogeneic cells is likely to expand in the future to include other cell types such as hepatocytes, myoblasts, and stem cell–derived replacement cells. Transplants originating from a member of the same species are referred to as *allotransplants.* However, many believe that transplants from other species, termed *xenografts,* represent a promising solution to the severely inadequate supply of allogeneic organs and tissues, and such grafts may be used in the future.

ANTIGENS IN TRANSPLANTATION

The major antigens recognized during graft rejection and the cell types targeting them are summarized in Table 48-1.

Major Histocompatibility Antigens

The major histocompatibility complex (MHC; Chapter 45)—consisting of human leukocyte antigens (HLAs) in humans—presents the strongest immunologic obstacle to all types of allografts. Because of its uniquely extensive polymorphism, truly MHC-identical, unrelated donors are difficult to find in an outbred species such as humans. The strong immunogenicity of allogeneic MHC molecules relates to the manner in which T cells are selected in the thymus; developing thymocytes do not survive unless they can weakly recognize a self-MHC/peptide complex on a thymic stromal cell. This process is termed *positive selection*. However, because thymocytes whose receptors have high affinity for self-MHC complexes are deleted, strongly autoreactive T cells rarely make it into the peripheral T-cell pool. Allogeneic antigens are not part of this *negative selection* process. The net result of these two selection steps is that the human T-cell "repertoire" is strongly biased to have cross-reactivity to allogeneic MHC molecules, providing a barrier to organ and hematopoietic cell transplantation. In the case of organ transplantation, in which long-term pharmacotherapy with powerful immunosuppressive drugs is used in an effort to prevent graft rejection, this can translate into improved results with matched organs in some situations. However, for unrelated, cadaveric donor transplantation, the benefits of HLA matching may be counterbalanced by the disadvantages associated with prolonged graft ischemia when attempts are made to transport organs to the most closely matched recipient. For HCT, the risks of GVH disease and marrow graft failure are so greatly amplified in the presence of extensive HLA mismatches that such transplants are generally avoided; if a sufficiently matched, related donor cannot be found, a search is conducted through large registries containing millions of volunteer unrelated donors.

Minor Histocompatibility Antigens

Minor histocompatibility antigens are peptides derived from polymorphic peptides presented by an MHC molecule. Even genotypically HLA-identical siblings have different minor histocompatibility antigens. These are sufficient to induce graft rejection if immunosuppressive pharmacotherapy is not used. In the case of HCT, significant GVH disease frequently (about 30 to 50% of the time) complicates transplantation between HLA-identical siblings, even with the use of pharmacologic immunoprophylaxis.

Other Antigens

The major blood group (ABO) antigens can be the target of a dramatic "hyperacute" rejection process that occurs when mismatched vascularized grafts are transplanted. Recognition of blood group antigens on the endothelial surface of the graft vessels by recipient "natural" antibodies (antibodies without known sensitization to the antigens) activates the complement and coagulation cascades, resulting in rapid graft thrombosis and ischemia. A similar outcome can occur after transplantation to an individual with preformed antidonor HLA antibodies resulting from presensitization by prior transplantation, transfusion, or pregnancy. Antibodies against other polymorphic antigens, such as MHC class I–related chain A, have been associated with graft rejection. Until recently, successful transplantation was not possible in the presence of a positive antidonor crossmatch. However, considerable success has now been achieved in the transplantation of ABO-mismatched kidneys, livers, and hearts (the last in the neonatal period only) and in the transplantation of kidneys to highly presensitized patients. In the case of kidney and liver transplantation, initial removal of the antibody and sometimes depletion of B cells, as well as the infusion of intravenous immunoglobulin, have led to success. ABO-mismatched neonatal heart transplantation has been successful because the transplant is performed before the recipient has developed high levels of anti–blood group antigen antibodies, and the B cells seem to be rendered tolerant to the donor blood group antigen by the grafting process. Recognition of blood group antigens can also be of significance in HCT, in which ABO barriers are routinely crossed in both directions. This can cause hemolysis of recipient erythrocytes if the mismatch is in the GVH direction, but this complication can be avoided by washing the cellular product before infusion. Mismatches in the HVG direction can cause more persistent problems due to ongoing destruction of donor erythropoietic cells, resulting in pure red cell aplasia. More often, however, donor erythropoiesis is established, and antidonor isohemagglutinins disappear from the circulation.

A and B blood group antigens are caused by the presence or absence of specific glycosylation enzymes in different individuals. Likewise, an antigenic specificity of the utmost importance in xenotransplantation is a carbohydrate epitope, Galα1-3Galα1-4GlcNAc (αGal), which is produced by a specific galactosyl transferase. Humans and Old World monkeys lack a functional αGal transferase and produce high levels of natural antibodies against the ubiquitous αGal epitope. Because animals of interest as xenograft sources (e.g., pigs) express αGal at high levels on their vascular endothelium, transplantation of vascularized organs from pigs results in hyperacute rejection unless something is done to absorb the antibodies or inactivate complement. The recent development of αGal-knockout pigs is therefore an important milestone, and encouraging results have been obtained in initial studies of pig-to-primate transplantation.

In another type of transplant reaction, recognition as foreign results not from the presence of an antigen but, paradoxically, from the absence of a self-MHC molecule. Natural killer (NK) cells express a series of surface inhibitory and activating receptors that determine, collectively, whether the NK cell does or does not kill a potential target cell. The ligands for the inhibitory receptors are MHC class I molecules, and the receptors recognize

specific groups of alleles. An NK cell may kill an allogeneic target that lacks a self-MHC inhibitory ligand. In animal models, this phenomenon results in rapid bone marrow rejection when the donor marrow cells are not given in excess numbers or when a fraction of them is destroyed by an incompletely suppressed T-cell response. A similar phenomenon has not been clearly demonstrated in clinical HCT. The possibility that NK cells play a role in organ allograft rejection has long been an area of controversy. NK cells may be of particular importance in xenotransplantation, where they appear early in infiltrates of organ xenografts undergoing acute vascular rejection. NK cells clearly play a strong role in the rejection of xenogeneic bone marrow, an observation that is relevant in one approach to inducing tolerance (see the later discussion).

MECHANISMS OF REJECTION AND GRAFT-VERSUS-HOST DISEASE

Cellular Mediators

Many different cell types participate in rejection responses, and there is considerable redundancy. T cells are key players in most forms of rejection, with the exception of rejection that can be induced by antibodies in the absence of T-cell help. These include hyperacute and acute vascular rejection processes that may be induced by natural antibodies, as described earlier, or by antibodies that are present due to presensitization. The possible role of NK cells has already been discussed.

Direct and Indirect Allorecognition

T-cell responses are induced by antigen-presenting cells (APCs) that present alloantigens. There are two forms of alloantigen recognition—direct and indirect (Fig. 48-1). Direct allorecognition denotes recognition of donor antigens on donor APCs provided by the graft. The extraordinarily high frequency of T cells with alloreactivity is caused by direct recognition of allogeneic MHC. Indirect recognition is the recognition of donor antigens that are picked up and presented on recipient MHC molecules on recipient APCs. The indirect response is more similar to "normal" T-cell responses, in which professional APCs present peptide antigens to T cells that are present at relatively low frequency in the naïve repertoire.

Direct alloreactivity is particularly important in the early post-transplantation period, when APCs within the transplanted organ are still present; many of these cells migrate to the lymphoid tissues, where they initiate the alloresponse. However, the APC supply that comes with the donor graft is not renewable; therefore, if the direct response is not maintained by the recognition of donor antigens on endothelial cells or other cells in the graft, it recedes in importance. The indirect response, in contrast, can be maintained by the constantly renewed pool of recipient APCs. The indirect response is of particular importance in inducing antibody responses.

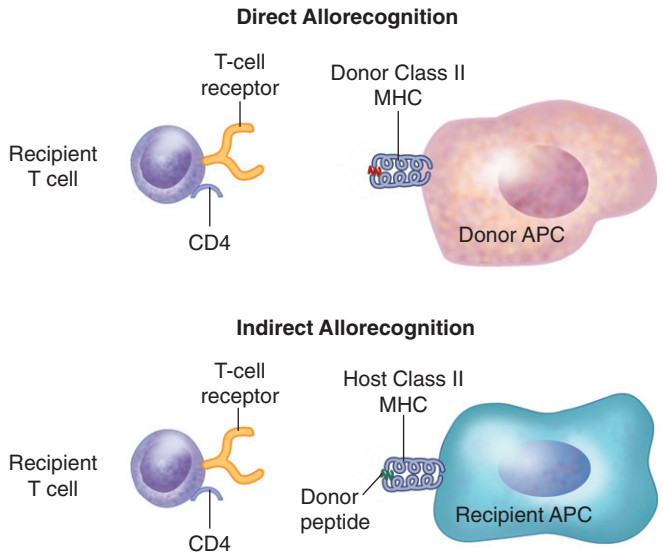

FIGURE 48-1. Direct and indirect allorecognition. Direct allorecognition involves the recognition by a T-cell receptor of major histocompatibility complex (MHC) molecules (with or without a peptide) on a donor antigen-presenting cell (APC). Indirect allorecognition involves recognition by the T-cell receptor of a donor peptide presented on a recipient APC that has picked up and processed donor antigens.

Effector Mechanisms of Rejection

T cells can promote graft rejection through several effector mechanisms. One is the antibody-dependent processes that have already been discussed, which can be induced by $CD4^+$ helper T cells that promote the differentiation and immunoglobulin (Ig) class switching of B cells that recognize other specificities on the same alloantigens. T cells provide cognate help to B cells when they recognize complexes of self-MHC with donor MHC-derived peptide antigens (produced by B cells whose surface Ig receptors recognize and pick up the donor MHC antigen). If antidonor antibody is not present before transplantation but is induced afterward, the response can lead to the pathologic picture of acute humoral rejection. Antibodies may also participate in a slower, poorly understood process of chronic rejection, which, in the case of kidney and heart transplantation, is characterized by unique vascular lesions with intimal thickening and loss of the vessel space and, in the case of lung transplantation, by obliterative bronchiolitis. The mechanisms underlying these chronic rejection lesions are not well understood, and several different immune processes may in fact lead to similar lesions.

Another major effector pathway leading to graft rejection involves cytotoxic T lymphocytes (CTLs), which are predominantly members of the $CD8^+$ T-cell subset but also include $CD4^+$ T cells. Several effector mechanisms lead to the killing of target cells by CTLs; these include the granzyme/perforin-mediated pathway and the pathways involving Fas/Fas ligand (FasL) and other members of the tumor necrosis factor (TNF) receptor family and their ligands (Chapter 46). Because $CD8^+$ cells recognize MHC class I molecules, which are widely expressed, it is not difficult to envision graft destruction by $CD8^+$ CTLs. $CD8^+$ CTLs may be activated via an APC that is initially stimulated through contact with an alloreactive $CD4^+$ cell. This is one form of CD4 "help" for $CD8^+$ cells. In addition, $CD8^+$ cells may be dependent on cytokines such as interleukin-2 (IL-2) from $CD4^+$ cells for their expansion and cytotoxic differentiation. However, there are also many examples of $CD8^+$ cell-mediated rejection that is independent of "help" from $CD4^+$ cells. MHC class II, which is recognized by $CD4^+$ T cells, is less widely expressed on graft tissues than is MHC class I, although it may be induced on endothelial cells and graft parenchymal cells in the presence of inflammatory cytokines such as interferon-γ (IFN-γ).

In addition to cytotoxic mechanisms resulting from direct allorecognition, $CD4^+$ and $CD8^+$ T cells with indirect specificity seem to be capable of causing graft destruction under some circumstances. Cytokines such as IFN-γ have been implicated in some instances, but the pathways of indirect graft destruction are not well understood. A $CD8^+$ cell-mediated form of skin graft rejection dependent on donor antigens cross-presented on recipient MHC molecules (a form of indirect allorecognition for $CD8^+$ cells) has been described in an animal model. This form of graft rejection may be directed at antigen presented on the endothelial cells of recipient vessels that revascularize the graft. This mechanism would not apply to primarily vascularized organ allografts.

The Role of T-Cell Trafficking

All the rejection processes described require trafficking of T cells into the graft. This process is made possible after the initial activation of naïve T cells in the lymphoid tissues. Naïve T cells can migrate into lymph nodes because of their expression of the CCR7 chemokine receptor and the adhesion molecule L-selectin. These T cells are activated by migratory graft APCs that also enter the lymph nodes. T-cell activation is associated with the loss of CCR7 and L-selectin expression and the acquisition of a new set of chemokine receptors and adhesion molecules that allow rolling and adhesion on the graft endothelium and entry into the graft parenchyma (Chapter 46). Inflammation in the graft, such as that induced by ischemia-reperfusion injury and the transplantation procedure itself, as well as that induced by initially responding T cells, is associated with the upregulation of chemokines and adhesion ligands that promote the entry of lymphocytes into the graft. Nevertheless, well-healed grafts can be slowly rejected by adoptively transferred memory T cells, demonstrating that acute graft injury and inflammation are not essential for rejection in the presence of an established memory T-cell response. Rejection of hematopoietic cell grafts may involve many of the same mechanisms involved in solid organ rejection, although less work has been done in this area.

Mechanisms of Graft-versus-Host Disease

Initiation of GVH disease (Chapter 181) requires that donor T cells recognize host alloantigens. The disease attacks a variety of recipient epithelial

TABLE 48-2 EXPERIMENTAL STRATEGIES TO PREVENT GRAFT-VERSUS-HOST DISEASE

STRATEGY	ADVANTAGES	LIMITATIONS
Donor T-cell T_H2 polarization (e.g., conditioning with ATG and TLI, in vitro stimulation with cytokine exposure)	May preserve GVL	May limit GVL; T_H2 can contribute to acute and chronic GVHD
Tolerance induction of donor T cells (e.g., costimulatory blockade, regulatory cells)	Some strategies may selectively tolerize GVH-reactive T cells (e.g., in vitro antigen exposure with costimulatory blockade)	Global immunosuppression may limit GVL and anti-infectious immunity; tolerance (i.e., GVH protection) may be incomplete
Donor T-cell depletion plus NK-cell infusion with class I mismatched transplantation	NK cells do not cause GVHD but may mediate antitumor effects; donor NK cells may eliminate host APCs that trigger GVHD	May require very large numbers of donor NK cells; antitumor effect may not apply to all tumors; requires appropriate MHC disparity and expression of polymorphic NK cell receptors; insufficient T-cell immunity to infection
Donor T-cell depletion followed by delayed DLI	Preserves high level of GVL due to GVH reactivity; GVHD does not occur if host inflammation from conditioning has subsided and initial HCT was devoid of donor T cells	Antitumor effect delayed until time of DLI; most applicable for indolent lymphohematopoietic tumors; GVHD more difficult to control in humans than in animal models
Depletion of donor T cells recognizing host alloantigens by in vitro activation/depletion (i.e., "allodepletion")	Preserves anti-infectious immunity and tumor antigen-specific responses	Loss of GVH reactivity limits GVL; highly efficient allodepletion methods not yet available; residual T cells may cause GVHD
Donor T-cell depletion with infusion of expanded infection-specific T cells (e.g., CMV or EBV-specific)	Reduced GVHD potential while protecting against significant infectious organisms	Lack of GVL effect; lack of broad anti-infectious immunity; expense and inefficiency of in vitro T-cell expansion; loss of survival/homing potential of cultured T cells
Donor T-cell depletion with infusion of expanded tumor antigen-specific T cells	GVL without GVHD	Lack of anti-infectious immunity; expense and inefficiency of in vitro expansion of tumor-specific T cells; loss of survival/homing potential of cultured T cells
Insertion of suicide gene (e.g., thymidine kinase) into donor T cells	Drugs targeting inserted gene (e.g., gancyclovir) kill donor T cells to treat GVHD after GVL initiated	Expense and inefficiency of in vitro transduction of T cells; loss of function/survival/homing potential of cultured T cells; risk of GVHD if transduction incomplete; curtailment of GVL when donor T cells killed in vivo
Block T-cell trafficking to epithelial GVHD target tissues (e.g., blockade of adhesion molecules or chemokines, sphingosine 1 phosphate agonists)	Permits lymphohematopoietic GVH reactions to occur, with associated GVL effects	Redundancy of trafficking pathways in inflammatory environment may limit efficacy; tumors outside of lymphohematopoietic system not targeted
Block injury/promote repair in epithelial target tissues (e.g., keratinocyte growth factor)	Permits lymphohematopoietic GVH reactions to occur, with associated GVL effects	Efficacy may be limited

APC = antigen-presenting cell; ATG = antithymocyte globulin; CMV = cytomegalovirus; DLI = donor lymphocyte infusion; EBV = Epstein-Barr virus; GVH = graft versus host; GVHD = graft-versus-host disease; GVL = graft-versus-leukemia effects; HCT = hematopoietic cell transplantation; MHC = major histocompatibility complex; NK = natural killer; T_H2 = helper T lymphocytes type 2; TLI = total lymphoid irradiation.

tissues, including the skin, intestine, and liver. Animal models have demonstrated clear roles for both $CD4^+$ and $CD8^+$ cells in initiating GVH disease, and each subset can do so independently of the other. The mechanisms of GVH disease include activation of alloreactive donor T cells by recipient APCs, leading to the differentiation of effector cells with direct cytotoxic activity and cytokine production in response to host antigens. A prominent role is played by TNF-α, whose production is induced in part by the translocation of bacteria across the intestinal wall, promoting activation of the innate immune system via toll-like receptors (Chapter 44). An intensely proinflammatory environment is produced by the combination of conditioning-induced tissue injury and disruption of mucosal barriers, bacterial activation of the innate immune system, and the GVH alloresponse. It is now appreciated that the inflamed microenvironment in target tissues plays an important role in promoting the trafficking of GVH-reactive T cells into these tissues.

STRATEGIES TO PREVENT GRAFT-VERSUS-HOST DISEASE

In view of the critical role of donor T cells in inducing GVH disease (Chapter 181), an obvious strategy to prevent this complication is to remove mature T cells from the marrow graft. In both animal models and clinical studies, this approach has been effective in preventing GVH disease; however, it has several disadvantages. One is that adult humans, particularly those who have undergone prior chemotherapy and radiotherapy, have little remaining thymic tissue and therefore demonstrate sluggish T-cell recovery, leading to serious opportunistic infections.

The second disadvantage applies to the most common indication for allogeneic HCT—the treatment of hematologic malignancies (Chapter 181). In this setting, T-cell depletion is often associated with an increased relapse rate due to the loss of a graft-versus-tumor effect, which is in large part mediated by GVH alloreactivity. Separation of GVH disease from graft-versus-tumor effects is a major goal of research in HCT, and some promising strategies are being explored (Table 48-2). These include the control of T-cell trafficking so that the GVH alloresponse is confined to the lymphohematopoietic tissues where the tumor resides, as well as host conditioning with total lymphoid irradiation in combination with antithymocyte globulin in an attempt to enrich NKT cells, which may inhibit GVH disease without impeding graft-versus-tumor effects.

The third disadvantage of donor T-cell depletion in HCT is that it increases the rate of engraftment failure. GVH alloreactivity and a "veto" effect of donor T cells help overcome host resistance to donor engraftment. A "veto" cell, which may be a T cell or an NK cell, kills a CTL that recognizes it. Although this phenomenon has been well established in animal models, its mechanisms have not been clearly determined, and its potential role in humans is uncertain. NK-cell recognition in the GVH direction, resulting from the absence in the recipient of an MHC class I ligand (E-Fig. 48-1) that can trigger a donor NK-cell inhibitory receptor (KIR), may promote donor marrow engraftment and antitumor effects in the setting of T-cell–depleted, HLA-mismatched HCT.

Clinically, pharmacologic immunosuppressive prophylaxis is usually used for at least 6 months after HCT to minimize the complication of GVH disease. Additionally, HLA-matched or closely matched donors are chosen whenever possible, because GVH disease increases in frequency and severity as more HLA barriers are transgressed. These measures are insufficient, however, and GVH disease remains a major complication of HCT. Therefore, many of the new strategies being explored in organ transplantation and other fields are also being examined for the prevention of GVH disease in experimental models. It should be borne in mind, however, that donor T cells' tolerance to recipient alloantigens (see the later discussion) might not be entirely beneficial in the setting of HCT for the treatment of malignant disease, because the loss of GVH alloreactivity is likely to come with a loss of antitumor effects.

STRATEGIES TO PREVENT ALLOGRAFT REJECTION

Nonspecific Immunosuppression

Immunosuppressive drugs are the mainstay of clinical organ transplantation, and improvements in these drugs have allowed the transplantation of hearts, lungs, pancreatic islets, and livers. The mechanisms of action of these agents are discussed in Chapter 34. However, it is noteworthy that despite these improvements and their enormous impact on early graft survival, these agents have been less effective in attenuating late graft loss. Because chronic immunologic rejection processes and the side effects of immunosuppressive drugs themselves are responsible for much of this late graft loss, better immunosuppressive agents and the induction of immune tolerance (see the later discussion) are major research goals.

Costimulatory Blockade

As our understanding of immune responses has increased, efforts to improve allograft survival have focused on numerous biologic agents, including antibodies and small molecules that target receptors of the immune system, as well as cell-based therapies. Because of the central role played by T cells in the immune response, considerable attention has been paid to blockers of T-cell costimulation. When a naïve T cell recognizes antigen through its unique T-cell receptor, additional costimulatory signals are required to allow full activation, expansion, and differentiation to occur. These signals are often provided by APCs in the form of ligands (e.g., B7-1, B7-2) for costimulatory receptors (e.g., CD28) on the T cell. Cross-talk between the T cell and the APC (e.g., due to CD40 activation by CD154 upregulation on the activated T cell) further amplifies the costimulatory activity of the APC, allowing it to effectively activate other T cells as well. The CD154 (T cell)–CD40 (B cell) interaction also promotes Ig class switching and the functioning of B cells as APCs. Blockade of these processes (e.g., by CTLA4Ig and anti-CD154 monoclonal antibodies) has led to marked prolongation of allograft survival in stringent rodent and large-animal models. Robust, systemic tolerance to donor antigens has been achieved in rodents receiving bone marrow transplants with costimulatory blockade and little or no additional conditioning. Some of these agents have been or are currently being evaluated in clinical trials of transplantation and autoimmune diseases. Anti-CD154 antibodies have been associated with thromboembolic complications, however, and their evaluation in transplantation trials is currently on hold. Numerous additional costimulatory and inhibitory pathways that affect T-cell responses have been described, and these are all potential targets for further manipulation of the alloresponse.

Immune Tolerance

Immune tolerance denotes a state in which the immune system is specifically unreactive to the donor graft (or recipient, in the case of GVH reactivity), while remaining normally responsive to other antigens. Tolerance is distinct from the state produced by nonspecific immunosuppressive agents, which increases the risk of infection and malignancy. Numerous approaches to tolerance induction have been described in rodent models, largely owing to the strong tolerogenicity of primarily vascularized heart, liver, and kidney grafts in these animals. Because such grafts are less tolerogenic in humans, none of these strategies has been applied clinically to date. Therefore, tolerance strategies that are appropriate for clinical evaluation must first be tested in stringent models, including relatively nontolerogenic grafts such as MHC-mismatched skin in rodents and vascularized organ graft models in large animals. In most of the models, only a superficial understanding of the mechanisms leading to tolerance has been achieved.

The three major mechanisms of T-cell tolerance are deletion, anergy, and suppression (often referred to as *regulation*). *Deletion* denotes the destruction of T cells with receptors that recognize donor antigens; it can be achieved during T-cell development in the thymus, for example, by the induction of mixed chimerism in T-cell–depleted hosts. Deletion can also be applied to mature T cells in the periphery, for example, by transplantation of a tolerogenic organ or marrow graft in combination with blockade of costimulatory molecules. *Anergy* denotes the inability of T cells to respond fully to antigens they recognize, and it can be induced by antigen presentation without costimulation. *Suppression* has attracted considerable interest since the discovery that constitutively $CD25^+$ T cells of the $CD4^+$ subset have suppressive activity that is dependent on expression of the transcription factor forkhead box protein 3 (Foxp3). These and other types of suppressive T cells (e.g., NKT cells) have been implicated in rodent transplantation tolerance models and in the prevention of autoimmunity. However, it seems likely that large numbers of regulatory cells recognizing the relevant antigens would be needed to apply this type of cellular therapy clinically, and the ultimate practicality of the approach remains to be determined. Nevertheless, an improved understanding of this type of immune regulation may lead to effective strategies for activating or expanding regulatory T cells in vivo, thereby favoring the suppressive immune response over destructive alloimmunity.

These developments in animal models and in the understanding of immune mechanisms have encouraged efforts to achieve immune tolerance in the setting of clinical transplantation. Every transplantation center has anecdotal cases of patients who have removed themselves from chronic immunosuppression without experiencing graft rejection. However, for every such patient, there are dozens more who have experienced rejection episodes with dose reductions or discontinuation of immunosuppressive drugs. Although trials of minimization and slow withdrawal of nonspecific immunosuppressive therapy are under way in organ transplant recipients, a major limitation is the absence of good predictors of success. It remains to be seen whether recently identified molecular "tolerance signatures" will provide markers with sufficient predictive value to allow such withdrawal to be undertaken safely.

One approach developed in animal models has been successfully applied to the induction of immune tolerance in a small group of patients receiving renal allografts. This approach involves bone marrow transplantation after nonmyeloablative conditioning, which is much less toxic than standard HCT conditioning. It was shown to be effective in the most stringent rodent and large-animal models before being evaluated clinically. Initial success using combined kidney and bone marrow transplantation in patients with renal failure due to multiple myeloma led to pilot studies in patients with renal failure without malignant disease, with encouraging preliminary results. This approach and others that have emerged from ongoing investigations provide hope that, in the future, transplant recipients might not need chronic immunosuppressive therapy, with its attendant complications and its limited ability to control chronic rejection. Because autoimmune diseases are major contributors to end-stage renal disease, diabetes, and other types of organ failure, the potential of tolerance strategies to reverse autoimmunity while inducing allograft tolerance is a source of hope for those patients as well. All these approaches must be undertaken with the caution, however, because successful regimens could lead to immune tolerance to active infectious organisms as well.

COMPLEMENT IN HEALTH AND DISEASE

DAVID R. KARP AND V. MICHAEL HOLERS

The complement system consists of more than 30 serum and membrane proteins that participate in both host defense and a wide variety of pathologic states. This system serves many protective functions ascribed to the innate immune system (Chapter 44). It helps to maintain blood sterility by depositing the membrane attack complex (MAC) in bacterial cell walls and lysing them. It also participates in the opsonization of pathogens for phagocytic

removal. The peptide *anaphylatoxins* produced during complement activation promote inflammatory responses with microbicidal effects. The deposition of complement on immune complexes helps to keep them soluble and remove them from the circulation.

There also is increasing evidence that complement can shape the adaptive immune response (Chapter 44). Antigens decorated by complement proteins are taken up by B cells and other antigen-presenting cells, resulting in T-cell activation. Complement activation is needed for optimal antibody production by B cells. Lastly, humans and experimental animals that are deficient in early complement components are often predisposed to autoimmune diseases, particularly systemic lupus erythematosus (SLE) (Chapter 274). This observation suggests that complement is required in some way to identify soluble self-antigens and eliminate self-reactive B cells.

Complement is activated immediately on exposure to immune complexes, but it lacks the immunologic memory of T or B cells with clonotypic receptors that discriminate between self and non-self. Activated complement can be deposited on host and pathogenic surfaces. This potentially dangerous situation is controlled by a series of genetically, structurally, and functionally similar proteins termed the *regulators of complement activation* (RCA). These proteins provide species-specific downregulation of complement activation on host tissues.

Inappropriate complement action occurs when the nondiscriminating activating proteins function in excess of the regulatory proteins that limit damage on self-tissues. This can be seen in almost any inflammatory disease. Some conditions are obvious, such as autoimmune hemolytic anemia, lupus nephritis, and immune complex vasculitis. In other diseases, the role of complement may be contributory but is less clear. These include myocardial infarction, stroke, cardiopulmonary bypass, and hemodialysis. Table 49-1 lists conditions in which complement activation is associated with pathology rather than protection.

In each of these conditions, inhibition of complement activation potentially would limit tissue damage. Many strategies have been developed to discover inhibitors that can work at various sites in the complement activation cascades for use as possible therapeutic agents in human diseases. These potential complement inhibitors include small molecules designed similarly to traditional drugs and newer biologic agents, particularly antibodies that inhibit complement activation.

Although the complement system plays important roles in infection and inflammatory responses, it also has many deleterious effects that must be controlled in conditions ranging from immune complex injury to reproduction. The critical feature of complement-mediated pathology is the alternative pathway amplification loop. As shown in Figure 49-1, failure to control this response results in the generation of potent inflammatory signals and the recruitment of tissue-damaging neutrophils, monocytes, and mast cells. Because more than half of the proteins associated with the complement system are dedicated to the control of activation or effector functions, it is clear that discrimination between "self" and "non-self" must occur even in the innate immune system.

Knowledge of how complement is activated and how it can be controlled offers new opportunities for the development of therapeutic agents for human diseases. Recently, anti-C5 monoclonal antibody therapy has been approved for treatment of paroxysmal nocturnal hemoglobinuria (Chapter 163), and it is anticipated that within the next few years, many additional complement-targeted drugs will be approved for clinical use. The diseases most likely to be improved by complement inhibition are autoimmune and inflammatory injuries to retina and the kidney.

ACTIVATION OF COMPLEMENT

As an essential component of the innate immune system, complement is endowed with redundant yet carefully controlled activation pathways. The molecular events that occur during activation not only are responsible for the pathology of complement-associated disease states but also offer opportunities for the rational design of inhibitors. For simplicity, it is convenient to think of the different parts of the complement activation pathways as involving *recognition, convertase/amplification,* and *effector* mechanisms.

Classical Pathway

Although traditionally thought of as activated only by immune complexes containing immunoglobulin M (IgM) or IgG, the classical pathway has been shown to be activated by targets other than immune complexes (Fig. 49-2). Notably, apoptotic cells bind C1q and activate the C1 proteases. C1 also is

TABLE 49-1 PATHOLOGIC CONDITIONS PRIMARILY ASSOCIATED WITH COMPLEMENT ACTIVATION

Allotransplantation	Macular degeneration
Alzheimer's disease	Meconium pneumonitis
ARDS	Multiple sclerosis
Arthus reaction	Multisystem organ failure
Asthma	Myasthenia gravis
Bullous pemphigoid	Post–cardiopulmonary bypass
Burns	Psoriasis
Crohn's disease	Recurrent spontaneous abortion
Glomerulonephritis (many causes)	Rheumatoid arthritis
Hemodialysis	Septic shock
Hemolytic anemia	Stroke
Hereditary angioedema	Systemic lupus erythematosus
Immune complex vasculitis	Traumatic brain injury
Ischemia-reperfusion injury	Xenotransplantation

ARDS = adult respiratory distress syndrome.

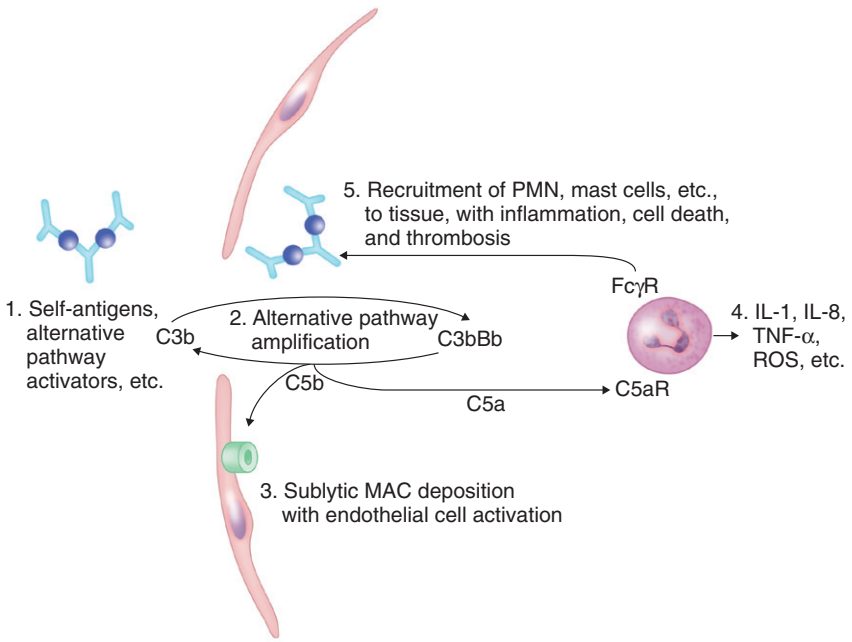

FIGURE 49-1. Pathogenic effect of complement. 1, Complement is activated by immune complexes or the exposure of surfaces that lack regulatory proteins. **2,** In the absence of effective regulation, the alternative pathway activation loop produces large amounts of both C5a and C5b. **3,** C5b initiates the deposition of sublytic amounts of the membrane attack complex (MAC), leading to cellular activation and proliferation. **4,** C5a is a potent chemoattractant and activator of polymorphonuclear neutrophils (PMN), mast cells, and other leukocytes, resulting in production of inflammatory cytokines and chemokines. **5,** Leukocytes also express Fc receptors (e.g., FcγR) that interact with immunoglobulin G bound to damaged tissue, further amplifying the generation of inflammatory mediators and activating coagulation pathways. IL = interleukin; ROS = reactive oxygen species; TNF-α = tumor necrosis factor-α.

Ag-Ab = antigen-antibody complex; C1-INH = C1 inhibitor; C4bp = C4-binding protein; CR = complement receptor; CRP = C-reactive protein; DAF = decay-accelerating factor; MCP = membrane cofactor protein; oxLDL = oxidized low-density lipoprotein; SAP = serum amyloid protein.

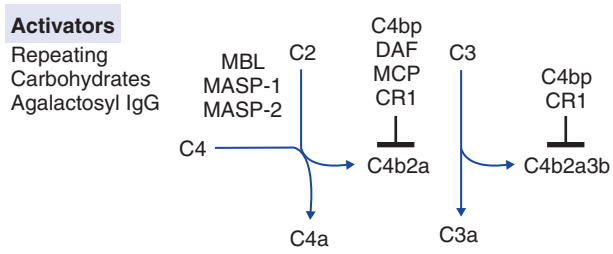

FIGURE 49-3. Schematic representation of the activation of the lectin pathway and generation in concert with the classical pathway of a C3 convertase. Included are naturally occurring regulators (inhibitors) of this pathway. CR = complement receptor; C4bp = C4-binding protein; DAF = decay-accelerating factor; IgG = immunoglobulin G; MASP = MBL-associated serine protease; MBL = mannose-binding lectin; MCP = membrane cofactor protein.

activated by the accumulated Aβ protein found in the neuritic plaques of patients with Alzheimer's disease. C-reactive protein (CRP) and serum amyloid protein bind to chromatin and other ribonucleoprotein complexes released from apoptotic cells. The CRP–nuclear antigen complexes bind and activate C1. C1q and the classical pathway appear to play a role in the opsonization and removal of nuclear materials that frequently contain autoantigens. The few patients with hereditary C1q deficiency all eventually develop SLE. The addition of CRP and enzymatically modified low-density lipoprotein to human serum causes the activation of complement, as determined by the almost quantitative conversion of C3 to C3b. Finally, deposits of CRP and activated C1 have been shown in infarcted human myocardium. Together, these observations suggest that activation through the antibody-independent classical pathway is important in protective immune responses and in pathogenic inflammatory reactions.

Regulation of the classical pathway activation occurs at several levels. First is the serine protease inhibitor (serpin), C1-inhibitor (C1-INH). C1-INH blocks the activity of many proteases, including factor XIIa, kallikrein, and factor XIa of the clotting system and C1r and C1s in the complement system. The importance of C1-INH is seen in hereditary angioedema (Chapter 260). In this instance, the heterozygous deficiency of C1-INH allows uncontrolled proteolysis of C2 and C4 after minor trauma. A vasoactive peptide is released from C2 and leads to painless (but occasionally life-threatening) soft tissue swelling. Treatment of acute attacks of hereditary angioedema includes purified C1-INH and antifibrinolytic drugs such as ε-aminocaproic acid.

Classical pathway activation also is regulated by RCA proteins. These proteins form the basis for the ability of the complement system to discriminate self from nonself targets. They are discussed in depth later in this chapter. The RCA proteins C4-binding protein (C4-bp) and complement receptor 1 (CR1) provide classical pathway regulation.

Lectin Pathway

The most recently described complement recognition and activation pathway is the lectin pathway (Fig. 49-3). The protein mannose-binding lectin (MBL) is a member of the collectin family that includes pulmonary surfactants A and D. MBL has a structure similar to C1q, in that it consists of several subunits, each having a globular recognition domain and a collagen-like portion that interacts with serine proteases. In the case of MBL, the globular domain is a lectin that binds to repeating carbohydrates (mannose and *N*-acetylglucosamine) on the surface of pathogens. Many microorganisms are recognized by MBL, including gram-positive and gram-negative bacteria, mycobacteria, fungi, parasites, and viruses, including human immunodeficiency virus 1 (HIV-1). In general, mammalian glycoproteins and glycolipids are not recognized by MBL. One notable exception is agalactosyl IgG. The levels of this modified immunoglobulin are increased in inflammatory conditions such as rheumatoid arthritis, raising the possibility that excessive activation of the lectin pathway is clinically relevant.

Three serine proteases, MASP-1, MASP-2, and MASP-3, associate with MBL, presumably through the collagen-like domain. Although not formally proved, this is analogous to the association of C1r and C1s with C1q. Activation of MASP-1 and MASP-2 results in cleavage of C2 and C4, with the subsequent formation of the classical pathway C3 convertase (C4b2a).

Variation in the structural and regulatory portions of the MBL gene leads to wide individual differences in serum levels. Low levels of MBL have been associated with recurrent infections in children and adults and have been shown to be a minor risk factor for the development of SLE. More striking is the association of low levels of MBL with infection in SLE. In a study of Danish lupus patients, heterozygous MBL deficiency was associated with a fourfold increase in the risk of bacterial pneumonia, and homozygous deficiency with a more than 100-fold increase.

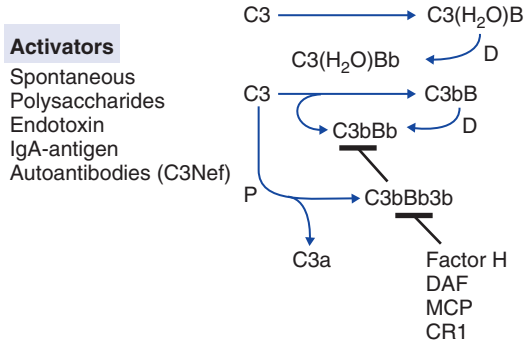

FIGURE 49-4. Schematic representation of the activation of the alternative pathway and generation of its C3 convertase. Included are naturally occurring regulators (inhibitors) of this pathway. C3Nef = C3-nephritic factor; CR = complement receptor; DAF = decay-accelerating factor; IgA = immunoglobulin A; MCP = membrane cofactor protein.

Alternative Pathway

The alternative pathway is much less stringent in its recognition requirements. It takes advantage of the fact that C3 undergoes spontaneous low-grade activation in the fluid phase (Fig. 49-4). This allows the covalent attachment of C3 to the polysaccharides of fungi and bacteria and to other appropriately charged targets, such as endotoxin and virally infected cells. Other alternative pathway activators include IgA immune complexes and biomaterials, such as cardiopulmonary bypass and hemodialysis membranes.

During spontaneous activation, called *tickover*, C3 acquires a C3b-like conformation and binds factor B, which is cleaved by the serine protease factor D to form the alternative pathway C3 convertase C3bBb. This complex has a short half-life. It is stabilized by properdin (factor P) during physiologic complement activation. This convertase cleaves more C3, which leads to additional C3bBb production. In fact, the C3b can also come from either the classical or alternative pathway. Thus, the activation of complement from any of the three pathways is greatly amplified. The alternative pathway C3 convertase is negatively regulated by the RCA proteins factor H, decay-accelerating factor (DAF), and CR1.

The central role of the alternative pathway as an essential amplifier of complement activation is borne out in its association with a number of clinicopathologic states. For example, membranoproliferative glomerulonephritis type II (Chapter 123) is associated with excessive C3 deposition in the kidney due either to the presence of autoantibodies (C3 nephritic factor) that stabilize the alternative C3 convertase or to genetic deficiencies in the complement regulatory proteins factor H and factor I. Likewise, the atypical form of hemolytic-uremic syndrome (i.e., not associated with shiga-like toxin) (Chapter 175) is found in families that harbor heterozygous mutations in factor H or I or have activating mutations in factor B or C3. Strong genetic associations have linked age-related macular degeneration (Chapter 431) to functional mutations in factor H as well as factor B and C3. Finally, rodent

models of many of the complement-associated diseases listed in Table 49-1 are ameliorated when the alternative pathway is genetically disrupted.

C3 and C5 Convertases

The three activation pathways converge at C3. C3 (and C4) contains a reactive glutamic acid residue buried within the three-dimensional structure of the protein. Normally the γ-carboxy group of the reactive glutamic acid in C3 (and C4) is linked to a nearby cysteine in an "internal thioester." On activation, the thioester is exposed to the surface of the protein, where it can react with amino or hydroxyl groups. Most of the thioesters are hydrolyzed by water to form inactive C3 or C4. Some of the thioesters form amide or ester bonds to proteins or carbohydrates, covalently attaching C3b (and C4b) to target surfaces. This enables cells bearing CR1 to bind these targets and opsonize them, representing one of the effector mechanisms of complement.

The covalently bound C3b associates with C4b2a (classical or lectin pathway) or with C3bBb (alternative pathway) to form a convertase for C5. C3b is part of the alternative-pathway C3 convertase, and its product generates an amplification loop that can deposit thousands of C3b molecules on a target, regardless of the initial activation step.

Regulators of Complement Activation

The major function of the protein regulators of complement activation (RCA) (E-Fig. 49-1) as a group is to limit the production of C3b by either the classical or the alternative C3 convertases. Because the addition of C3b to a C3 convertase makes it a C5 convertase, regulation of the two enzyme complexes is linked. Modulation of their activity on host cells limits tissue destruction and the production of inflammatory mediators.

There are six RCA proteins that control the C3/C5 convertases, listed in Table 49-2. The genes for all of these proteins are found in a cluster on human chromosome 1.q32. Structurally, they are composed of repeating subunits termed *short consensus repeats* (SCRs), sometimes referred to as *complement control protein* modules. Each SCR has about 60 amino acids with four invariant cysteine residues. The pairing of the disulfides leads to a four- to five-β pleated sheet structure, causing the SCRs to appear like beads on a string.

Although the SCRs are structurally related, the individual RCA proteins may recognize different parts of the C3 molecule. They do so using specific combinations of SCRs. The RCA proteins function to control complement activation by two processes. First is *decay acceleration*. This refers to the process whereby the RCA protein binds to C3b or C4b in the convertase and dissociates the other members of the complex, rendering it enzymatically inactive. The second effect is *cofactor* activity. Some of the RCA proteins facilitate the recognition of C3b or C4b by a serum protease, factor I. Cleavage of C3b or C4b by factor I renders the convertase irreversibly inactive.

Despite their relatedness, the RCA proteins exhibit differences in their overall structure, distribution, and function (see Table 49-2). All of the RCA proteins except MCP and CR2 have decay acceleration activity; it is the only function of DAF. This glycosyl phosphatidylinositol-linked protein is widely expressed and causes the removal of C2a or Bb from the C3 and C5 convertases. DAF lacks the cofactor activity seen with the other RCA proteins (except CR2). Factor H and C4bp are serum proteins. MCP and DAF are ubiquitously expressed membrane proteins. CR1 and CR2 are membrane proteins expressed primarily on hematopoietic cells.

RCA proteins have been linked to several disease states. DAF is missing from the abnormal erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (Chapter 163). Although the hemolysis of these cells is ultimately due to the fact that the cells also lack CD59 (see later discussion), the DAF deficiency promotes complement activation on these cells. The association between genetic factor H deficiency and type II membranoproliferative glomerulonephritis and familial hemolytic-uremic syndrome has been mentioned. Lastly, low levels of CR1 and/or CR2 have been seen in patients with SLE. CR1 has cofactor and decay activity, and its major role is in the removal of immune complexes from the circulation. CR2 is necessary for optimal B-cell regulation, including the downmodulation of autoreactive B cells.

TABLE 49-2 DISTRIBUTION AND FUNCTION OF REGULATORS OF COMPLEMENT ACTIVATION (RCA) PROTEINS

RCA PROTEIN	DISTRIBUTION	FUNCTION
C4-binding protein	Serum	Cofactor for C4b; decay of classical C3/C5 convertases
Factor H	Serum	Cofactor for C3b; decay of alternative C3/C5 convertases
Decay-accelerating factor	Widely distributed on most cell types	Decay of classical and alternative C3/C5 convertases
Membrane cofactor protein	Widely distributed on most cell types	Cofactor for C3b and C4b (not RBCs)
Complement receptor 1	Most blood cells; mast cells	Cofactor for C3b and C4b; decay of C3/C5 convertases; receptor for C3b/C4b
Complement receptor 2	B cells; follicular dendritic cells	Receptor for C3b fragments; regulation of B cells

RBCs = red blood cells.

Membrane Attack Complex

The cleavage of C5 by either convertase generates C5a, the most potent of the complement anaphylatoxins, and C5b. C5b associates with C6 and C7 to create a lipophilic trimer as part of the MAC (E-Fig. 49-2). On the surface of a target cell, fewer than 1% of the C5b67 trimers that are formed insert into the lipid bilayer and serve as binding sites for C8. This attracts C9 to the membrane, and C9 has the capacity to self-polymerize. A total of 12 to 18 C9 molecules form a ring structure, completing the MAC. In its complete form, the MAC appears like a doughnut with a 10-nm pore running through the center. This pore can allow water and ions to enter the cells, ultimately leading to cell lysis. A MAC with only one or two C9 molecules also can cause lysis, however, suggesting that the MAC disrupts the lipid integrity in its general vicinity, rather than creating holes in the membrane.

The MAC itself appears to be largely redundant in terms of protection against infection. It appears to be essential only for efficient elimination of *Neisseria* species. Individuals who are homozygous deficient for C6, C7, or C8 are at risk for meningococcal and gonococcal infection (Chapters 306 and 307). C9 deficiency is the most common immunodeficiency in Japan, with a heterozygote frequency of 3 to 5%, which notably is not associated with an increased risk of *Neisseria* infection. Absence of an efficient MAC is not deleterious to the population in general and may have some selective advantage.

Extensive complement activation during an inflammatory response can result in sufficient MAC deposition to cause host cell lysis. Most nucleated cells have mechanisms to resist the osmotic changes caused by the MAC, however, and they may "disassemble" the MAC as it is formed. Rather, the nonlethal effects of sublytic MAC deposition are more likely to contribute to pathology. In most cells, this occurs through a general activation of multiple cell signaling pathways. Calcium enters the cell, activating protein kinases and phospholipase C, and upregulates the production of cyclic adenosine monophosphate (cAMP). G proteins and their associated factors are concentrated at the cell membrane, perhaps localized to C9 directly. The mitogen-activated protein kinase pathways (extracellular signal-regulated kinase [ERK], c-Jun N-terminal kinase [JNK], and p38) are activated, resulting in the induction of transcription factors such as c-jun and c-fos, cell proliferation, and inhibition of apoptosis.

The response to MAC deposition depends on the cell type (E-Table 49-1). In phagocytic cells, such as polymorphonuclear neutrophils or macrophages, sublytic MAC activation leads to the production of reactive oxygen species (e.g., superoxide, hydrogen peroxide), as well as prostaglandins and leukotrienes. Platelets undergo the exposure of phosphatidylserine on their outer membrane, facilitating formation of blood coagulation enzyme complexes with a potentially procoagulant effect. On endothelial cells, MAC deposition induces the synthesis of interleukin-1α (IL-1α), which leads to further autocrine and paracrine endothelial cell activation; stimulates a procoagulant state by altering the phospholipid composition of the endothelial membrane, inducing the synthesis of tissue factor and upregulating the synthesis of plasminogen activator inhibitor; induces the expression of adhesion molecules, including intercellular adhesion molecule 1 (ICAM-1) and E-selectin; and stimulates endothelial cells to proliferate through growth factor production. Despite the fact that cell death does not occur, deposition of the sublytic levels of MAC leads to a potentially more dangerous situation, with increased inflammation, coagulation, and cellular proliferation.

Regulation of MAC formation is important clinically and has become an area of therapeutic research. Two fluid-phase proteins, clusterin and S-protein (vitronectin), bind the C5b-7 complex and prevent its association with the lipid membrane. C8 and usually two to four C9 molecules bind to this soluble complex, termed *sC5b-9*, which is lytically inactive. CD59 is a membrane-bound inhibitor of MAC formation. This small glycoprotein is attached to the cell membrane through a glycosyl phosphatidylinositol tail. It binds tightly to C5b-8, preventing the binding and polymerization of C9. CD59 shows strong species restriction, being most effective in the inhibition of MAC formation by the same or closely related species. The expression of CD59 is defective in patients with paroxysmal nocturnal hemoglobinuria, owing to the failure to synthesize the glycosyl phosphatidylinositol tail on this and many other cell surface proteins, including DAF. The clinical features of paroxysmal nocturnal hemoglobinuria are protean. The hemolysis is believed to be caused by low-grade complement activation on red blood cells due to the lack of DAF; without CD59, MAC formation then proceeds and allows hemolysis (Chapter 163).

Anaphylatoxins

In addition to the MAC, the other major source of pathologic damage resulting from complement activation comes from the action of the anaphylatoxins. These are the peptides C3a, C4a, and C5a, which are cleaved from their respective proteins during activation. They were named by Friedberger in 1910 to describe toxic effects after the transfer of complement-activated serum into laboratory animals. They are 77 (C3a and C4a) or 74 (C5a) amino acids long and contain a carboxy (C)-terminal arginine. The structures of C3a and C5a have been determined by x-ray crystallography and nuclear magnetic resonance; they exhibit a compact amino (N)-terminal region that is held together by conserved disulfide bonds. This part of the molecule contains cationic amino acids that are believed to interact with the anaphylatoxin receptors. The C-terminal regions of the anaphylatoxins are extended sequences. Only the last five amino acids are required for activity. In plasma, the C-terminal arginine is removed rapidly by carboxypeptidase N from anaphylatoxins not bound to their receptors. Depending on the response studied, this removal totally inactivates the anaphylatoxin or reduces its potency by 1000-fold.

The C5a receptor (C5aR [CD88]) was the first anaphylatoxin receptor to be characterized. It is a seven-transmembrane-spanning protein that couples ligand binding to G-protein signaling. Expressed on myeloid cells, particularly neutrophils and eosinophils, it mediates the potent chemoattractant property of C5a for both of these cell types. Signaling through CD88 leads to rapid secretion of all granule contents. These include proteases, peroxidases, and lactoferrin from neutrophils, and peroxidase, major basic protein, and eosinophil cationic protein from eosinophils. C5a also induces the release of cytokines, such as tumor necrosis factor (TNF), IL-1, IL-6, and IL-8, and adhesion molecules, promoting the inflammatory response. The C5aR also has been found on numerous other tissues (E-Table 49-2). These include hepatocytes, bronchial and alveolar epithelium, vascular endothelium, renal mesangial and tubular epithelial cells, and brain neuronal cells. The function of C5a in these tissues is not clear. In vitro experiments have shown that these cells are activated by exposure to the anaphylatoxins, leading to production of cytokines, chemokines, and prostaglandins, and to cell proliferation.

The C3a receptor is also a seven-transmembrane-domain protein. It is expressed on almost all myeloid cells, including mast cells, where it mediates the release of allergic mediators. The C3aR also has been detected on many tissues, including in the brain.

The anaphylatoxins have many biologic effects. In general, they cause smooth muscle contraction and recruitment of granulocytes, monocytes, and mast cells. In theory, they can contribute to the pathophysiology of any inflammatory condition. C3a and C5a have been shown to play a role in diseases such as adult respiratory distress syndrome, multisystem organ failure, septic shock, myocardial ischemia-reperfusion injury, asthma, rheumatoid arthritis, SLE, and inflammatory bowel disease. The anaphylatoxin peptides also are responsible for the "postpump" syndrome seen in patients undergoing cardiopulmonary bypass or hemodialysis. Exposure of blood to dialysis or perfusion membranes leads to complement activation. Within minutes of starting bypass, there is a sharp increase in the levels of C3a and C5a in the extracorporeal circuit being returned to the patient. This increase can be associated with respiratory distress, pulmonary hypertension, and pulmonary edema. It has been shown that the length of time that patients stay on the ventilator after bypass surgery depends on the level of C3a generated during reperfusion.

C3a and C5a have been implicated in the initiation and prolongation of adult respiratory distress syndrome (Chapter 104) and multisystem organ failure (Chapter 106). After severe trauma (Chapter 112), levels of C3a have been measured that suggest activation of the entire circulating C3 pool. This activation leads to bronchoconstriction, increased vascular permeability, and vascular plugging with leukocytes. The activation of white blood cells continues the cycle of tissue damage with further complement activation. Continued elevation of C3a in shock or adult respiratory distress syndrome is a poor prognostic sign. C3a also appears to play a major role in the pathogenesis of asthma (Chapter 87).

COMPLEMENT INHIBITORS

Given the many disease states in which complement is one of the central mediators of pathology, it is no surprise that several complement inhibitors are in preclinical or clinical development for treatment of human diseases. These inhibitors take several different forms. Some are variations of physiologic inhibitors, whereas others are the products of molecular biologic searches for novel compounds.

It is important to consider where in the complement pathway to design an inhibitor to act. Inhibition of the activation pathways limits the production of biologically active peptides. All three pathways need to be inhibited, however, for this approach to be effective. Inhibiting the activation of C3 not only prevents the generation of the C3a anaphylatoxin but also may leave the patient susceptible to infection by limiting the deposition of C3b on targets as an opsonin. Inhibition of C3b deposition also theoretically would decrease the patient's ability to clear immune complexes, resulting in renal, pulmonary, and vascular damage. It also might promote the development of antibodies to self-antigens.

Inhibition of the C5 convertases is an attractive goal because it would prevent the generation of the C5a anaphylatoxin and the MAC. This strategy would inhibit complement activation from any cause without the potentially immunosuppressive effects of limiting C3b deposition. Inhibitors based on this concept are the farthest along in clinical treatment.

Other concerns about complement inhibition include whether it is short-term or long-term and whether it is systemic or localized. Long-term inhibition of complement, particularly at early steps, is likely to predispose the patient to infection. Short-term (hours to days) inhibition at any step is unlikely to cause problems. Given that inflammation is usually a local phenomenon, there are several mechanisms being tested to target complement inhibitors to these sites. In this way, higher levels of inhibition can be achieved where needed with lower doses of inhibitor.

Natural Complement Inhibitors

Naturally occurring compounds that control complement activation include products or extracts of plants, fungi, insects, venoms, and cell lines. The mechanism of complement inhibition by some of these natural products is known and is of clinical and experimental importance. Cobra venom factor isolated from *Naja naja* is a 144,000-D glycoprotein that forms an alternative pathway convertase in association with Bb; this leads to massive activation of complement that causes pulmonary microvascular injury in experimental animals. Perhaps the most widely used natural inhibitor of complement activation is heparin. It decreases activation of the classical and the alternative pathways. In clinical practice, the anticomplementary effect of heparin has been used to prevent complement activation during cardiopulmonary bypass. Measurement of complement activation products such as C3a or soluble C5b-9 after bypass showed decreases of 35 to 70% for adult and pediatric patients when heparin-coated extracorporeal circuits (e.g., Duraflo II) were used. Although numerous studies have looked at the decrease in complement activation by heparin-coated bypass circuits, there have been few attempts to correlate this with clinical outcome.

Anti-C5

The complement inhibitor that has achieved the widest attention as a therapeutic agent is a monoclonal antibody to C5. The advantage to this strategy is that it prevents the generation of C5a, the most potent of the anaphylatoxins, and of the MAC. The generation of C3b and C4b opsonins still would occur, allowing proper clearance of pathogens and immune complexes even if C5 conversion were inhibited chronically. Because there is evidence that activation of early complement components is important for the maintenance of tolerance to self-antigens, inhibition of C5 activation may be less worrisome than inhibition of C3 activation. Lastly, there appears to be little detrimental effect of genetic C5 deficiency. The only consequence

of C5 deficiency in humans seems to be an increased risk of *Neisseria* infection.

The anti-C5 monoclonal antibody eculizumab has been approved for use in patients with paroxysmal nocturnal hemoglobinuria to block intravascular hemolysis and stabilize hemoglobin levels.[1] Several groups have also reported the favorable use of an anti-C5 monoclonal antibody in animal model systems of arthritis and lupus nephritis.

Soluble CR1

Soluble CR1 (sCR1) was the first rationally designed complement inhibitor to undergo extensive testing. The idea behind the use of this RCA protein was that it had multiple mechanisms of action. It has two separate binding sites for C3b and one for C4b. It not only serves as a cofactor for the enzymatic degradation of C3b and C4b but also can dissociate the classical (C3b4b) and the alternative (C3b2) C5 convertases. It is produced by recombinant methodology in animal cells. A modified version, produced in a manner that decorates the protein with the carbohydrate sialyl Lewis^x, the ligand for P-selectin and E-selectin, targets sCR1 directly to activated (inflamed) endothelium. Another modified form of sCR1 targets the protein to the lipid membrane of cells. This technique has been shown to be experimentally effective in situations in which sCR1 can be delivered locally, such as intra-articular injections or the perfusion of donor organs before transplantation.

Soluble CR1 blocks activation of complement in many experimental animal models of disease, including myocardial ischemia-reperfusion injury, intestinal ischemia, and middle cerebral artery ligation in rodents. In each case, the administration of sCR1 was associated with decreased tissue injury, less neutrophil accumulation, and lower concentrations of inflammatory mediators such as leukotriene B_4. In allograft transplantation, the donor organ undergoes significant ischemia-reperfusion injury. Animal models of allogeneic renal and lung transplantation have shown that sCR1 prolongs graft survival, which may prevent early rejection episodes. In pig-to-primate cardiac xenotransplantation, sCR1 prolonged graft survival remarkably. In one study of human lung transplantation, patients were randomly assigned to receive or not receive a single infusion of 10 mg/kg of sCR1 before restoration of blood flow in the graft. Complement activation was suppressed for 2 days after surgery. There were trends for all patients toward decreased time on the ventilator and in the intensive care unit that did not reach statistical significance. For patients who had been receiving cardiopulmonary bypass during surgery (and may have had more complement activation), however, there was a 56% decrease in time spent on the ventilator postoperatively if they were treated with sCR1.

sCR1 has also been found to have salutary effects in animal models of autoimmune disease, including collagen-induced arthritis, experimental autoimmune neuritis, a model for Guillain-Barré syndrome, and models of myasthenia gravis, multiple sclerosis, and glomerulonephritis.

Transgenic Animals

Xenotransplantation offers a solution to the chronic lack of solid organs for transplantation. The most studied donor animal is the pig because swine have many desirable experimental and practical characteristics, such as size and ease of production. Although immunosuppression and other strategies may be able to overcome cellular immune barriers, the most pressing current problem facing xenotransplantation is hyperacute rejection. This is the immediate (within minutes) cessation of graft function owing to natural IgM antibodies that react with the vascular endothelium of the xenograft. The target of these antibodies is mainly the carbohydrate moiety galactose-(α1,3)-galactose present on the graft. These antibodies quickly activate complement, leading to intravascular coagulation, tissue edema, hemorrhage, and endothelial activation. Prevention of hyperacute rejection would require reducing the levels of antibodies or of their antigens, inhibiting complement activation, or a combination of all three. Because complement regulatory proteins display species specificity, the approach to limit complement activation in xenografts has been to make transgenic pigs that express one or more membrane proteins of human origin. In one study, kidneys from the triple-transgenic pigs were transplanted into bilaterally nephrectomized baboons. No immunosuppression or pretreatment of the recipients was given. Under these circumstances, the function of a nontransgenic pig kidney ceases within 3 minutes, and the graft rapidly becomes nonviable. The function of transgenic kidneys was maintained with good urine output for 3 to 5 days in the six baboons that received these grafts.

C3a and C5a Receptor Antagonists

The profound biologic effects of the anaphylatoxins and the many conditions in which C3a and C5a are believed to play a pathologic role make the development of specific inhibitors of these proteins attractive. Because the active portion of the anaphylatoxins is contained in the C-terminal part of the protein, it is possible that small-molecule antagonists could be developed that are orally available, easy to synthesize, and inexpensive. These are all advantages over the use of biologics such as monoclonal antibodies or recombinant RCA proteins. To date, several synthetic C5a antagonists have been described. C5a inhibitors are in early human clinical trials. Finally, a potent small-molecule inhibitor of C3a has been found to be active in vitro as an inhibitor of C3a-mediated cellular activation, chemotaxis, and smooth muscle contraction.

Anti–Factor B

Inactivation of the factor B gene in mice prevents a number of autoimmune or inflammatory diseases. Presumably, this represents the necessity for an intact alternative pathway to amplify subclinical complement activation. Inhibition of the alternative pathway activation loop is an attractive target for therapy because it would allow for protective immunity against pathogens through the classical pathway. The efficacy of this approach has been demonstrated using a monoclonal antibody to factor B that inhibits its function. This antibody blocks activation of the alternative pathway in the serum of a number of species, including mice, rats, nonhuman primates, and humans. In a mouse model of complement-mediated pregnancy loss, administration of the anti–factor B antibody resulted in a 50% decrease in fetal death. In models of asthma and renal ischemia-reperfusion injury, this antibody ameliorated disease. This strategy could have wide applicability in a number of disease states.

APPROACH TO THE PATIENT WITH POSSIBLE CARDIOVASCULAR DISEASE

LEE GOLDMAN

Patients with cardiovascular disease may present with a wide range of symptoms and signs, each of which may be caused by noncardiovascular conditions. Conversely, patients with substantial cardiovascular disease may be asymptomatic. Because cardiovascular disease is a leading cause of death in the United States and other developed countries, it is crucial that patients be evaluated carefully to detect early cardiovascular disease, that symptoms or signs of cardiovascular disease be evaluated in detail, and that appropriate therapy be instituted. Improvements in diagnosis, therapy, and prevention have contributed to a 70% or so decline in age-adjusted cardiovascular death rates in the United States since the 1960s. However, the absolute number of deaths from cardiovascular disease in the United States has not declined proportionately because of the increase in the population older than 40 years as well as the aging of the population in general.

In evaluating a patient with known or suspected heart disease, the physician must determine quickly whether a potentially life-threatening condition exists. In these situations, the evaluation must focus on the specific issue at hand and be accompanied by the rapid performance of appropriately directed additional tests. Examples of potentially life-threatening conditions include acute myocardial infarction (Chapter 73), unstable angina (Chapter 72), suspected aortic dissection (Chapter 78), pulmonary edema (Chapter 59), and pulmonary embolism (Chapter 98).

USING THE HISTORY TO DETECT CARDIOVASCULAR SYMPTOMS

Patients may complain spontaneously of a variety of cardiovascular symptoms (Table 50-1), but sometimes these symptoms are elicited only by obtaining a careful, complete medical history. In patients with known or suspected cardiovascular disease, questions about cardiovascular symptoms are key components of the history of present illness; in other patients, these issues are a fundamental part of the review of systems.

Chest Pain

Chest discomfort or pain is the cardinal manifestation of myocardial ischemia resulting from coronary artery disease or any condition that causes myocardial ischemia by an imbalance of myocardial oxygen demand compared with myocardial oxygen supply (Chapter 71). New, acute, often ongoing pain may indicate an acute myocardial infarction, unstable angina, or aortic dissection; a pulmonary cause, such as acute pulmonary embolism or pleural irritation; a musculoskeletal condition of the chest wall, thorax, or shoulder; or a gastrointestinal abnormality, such as esophageal reflux or spasm, peptic ulcer disease, or cholecystitis (Table 50-2). The chest discomfort of myocardial infarction commonly occurs without an immediate or obvious precipitating clinical cause and builds in intensity for at least several minutes; the sensation can range from annoying discomfort to severe pain (Chapter 73). Although a variety of adjectives may be used by patients to describe the sensation, physicians must be suspicious of any discomfort, especially if it radiates to the neck, shoulder, or arms. The probability of an acute myocardial infarction can be estimated by integrating information from the history, physical examination, and electrocardiogram (Fig. 50-1).

The chest discomfort of unstable angina is clinically indistinguishable from that of myocardial infarction except that the former may be precipitated more clearly by activity and may be more rapidly responsive to antianginal therapy (Chapter 72). Aortic dissection (Chapter 78) classically presents with the sudden onset of severe pain in the chest and radiating to the back; the location of the pain often provides clues to the location of the dissection. Ascending aortic dissections commonly present with chest discomfort radiating to the back, whereas dissections of the descending aorta commonly present with back pain radiating to the abdomen. The presence of back pain or a history of hypertension or other predisposing factors, such as Marfan syndrome, should prompt a careful assessment of peripheral pulses to determine whether the great vessels are affected by the dissection and of the chest radiograph to evaluate the size of the aorta. If this initial evaluation is suggestive, further testing with transesophageal echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI) is indicated. The pain of pericarditis (Chapter 77) may simulate that of an acute myocardial infarction, may be primarily pleuritic, or may be continuous; a key physical finding is a pericardial rub. The pain of pulmonary embolism (Chapter 98) is commonly pleuritic in nature and is associated with dyspnea; hemoptysis also may be present. Pulmonary hypertension (Chapter 68) of any cause may be associated with chest discomfort with exertion; it commonly is associated with severe dyspnea and often is associated with cyanosis.

Recurrent, episodic chest discomfort may be noted with angina pectoris and with many cardiac and noncardiac causes (Chapter 71). A variety of stress tests (Table 50-3) can be used to provoke reversible myocardial ischemia in susceptible individuals and to help determine whether ischemia is the pathophysiologic explanation for the chest discomfort (Chapter 71).

Dyspnea

Dyspnea, which is an uncomfortable awareness of breathing, is commonly due to cardiovascular or pulmonary disease. A systematic approach (see Fig. 83-3 in Chapter 83) with selected tests nearly always reveals the cause. Acute dyspnea can be caused by myocardial ischemia, heart failure, severe hypertension, pericardial tamponade, pulmonary embolism, pneumothorax, upper airway obstruction, acute bronchitis or pneumonia, or some drug overdoses (e.g., salicylates). Subacute or chronic dyspnea is also a common presenting or accompanying symptom in patients with pulmonary disease (Chapter 83). Dyspnea also can be caused by severe anemia (Chapter 161) and can be confused with the fatigue that often is noted in patients with systemic and neurologic diseases (Chapters 264 and 403).

In heart failure, dyspnea typically is noted as a hunger for air and a need or an urge to breathe. The feeling that breathing requires increased work or effort is more typical of airway obstruction or neuromuscular disease. A feeling of chest tightness or constriction during breathing is typical of bronchoconstriction, which is commonly caused by obstructive airway disease (Chapters 87 and 88) but also may be seen in pulmonary edema. A feeling of heavy breathing, a feeling of rapid breathing, or a need to breathe more is classically associated with deconditioning.

In cardiovascular conditions, chronic dyspnea usually is caused by increases in pulmonary venous pressure as a result of left ventricular failure (Chapters 58 and 59) or valvular heart disease (Chapter 75). Orthopnea, which is an exacerbation of dyspnea when the patient is recumbent, is due to increased work of breathing because of either increased venous return to the pulmonary vasculature or loss of gravitational assistance in diaphragmatic effort. Paroxysmal nocturnal dyspnea is severe dyspnea that awakens a patient at night and forces the assumption of a sitting or standing position to achieve gravitational redistribution of fluid.

Palpitations

Palpitations (Chapter 62) describe a subjective sensation of an irregular or abnormal heartbeat. Palpitations may be caused by any arrhythmia (Chapters 64 and 65) with or without important underlying structural heart disease. Palpitations should be defined in terms of the duration and frequency of the episodes; the precipitating and related factors; and any associated symptoms of chest pain, dyspnea, lightheadedness, or syncope. It is crucial to use the history to determine whether the palpitations are caused by an irregular or a regular heartbeat. The feeling associated with a premature atrial or ventricular contraction, often described as a "skipped beat" or a "flip-flopping of the heart," must be distinguished from the irregularly irregular rhythm of atrial fibrillation and the rapid but regular rhythm of supraventricular tachycardia. Associated symptoms of chest pain, dyspnea, lightheadedness, dizziness, or diaphoresis suggest an important effect on cardiac output and mandate further evaluation. In general, evaluation begins with ambulatory electrocardiography (ECG) (Table 50-4), which is indicated in patients who have palpitations in the presence of structural heart disease or substantial accompanying symptoms. Depending on the series, 9 to 43% of patients have important underlying heart disease. In such patients, more detailed evaluation is warranted (see Fig. 62-1).

Lightheadedness or *syncope* (Chapter 62) can be caused by any condition that decreases cardiac output (e.g., bradyarrhythmia, tachyarrhythmia, obstruction of the left ventricular or right ventricular inflow or outflow, cardiac tamponade, aortic dissection, or severe pump failure), by

TABLE 50-1 CARDINAL SYMPTOMS OF CARDIOVASCULAR DISEASE

Chest pain or discomfort
Dyspnea, orthopnea, paroxysmal nocturnal dyspnea, wheezing
Palpitations, dizziness, syncope
Cough, hemoptysis
Fatigue, weakness
Pain in extremities with exertion (claudication)

reflex-mediated vasomotor instability (e.g., vasovagal, situational, or carotid sinus syncope), or by orthostatic hypotension (see Table 62-1 in Chapter 62). Neurologic diseases (e.g., migraine headaches, transient ischemic attacks, or seizures) also can cause transient loss of consciousness. The history, physical examination, and ECG are often diagnostic of the cause of syncope (see Table 62-2 in Chapter 62). Syncope caused by a cardiac arrhythmia usually occurs with little warning. Syncope with exertion or just after conclusion of exertion is typical of aortic stenosis and hypertrophic obstructive cardiomyopathy. In many patients, additional testing is required to document central nervous system disease, the cause of reduced cardiac output, or carotid sinus

TABLE 50-2 CAUSES OF CHEST PAIN

CONDITION	LOCATION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS
CARDIOVASCULAR CAUSES					
Angina	Retrosternal region; radiates to or occasionally isolated to neck, jaw, epigastrium, shoulder, or arms (left common)	Pressure, burning, squeezing, heaviness, indigestion	<2-10 min	Precipitated by exercise, cold weather, or emotional stress; relieved by rest or nitroglycerin; atypical (Prinzmetal's) angina may be unrelated to activity, often early morning	S_3 or murmur of papillary muscle dysfunction during pain
Rest or unstable angina	Same as angina	Same as angina but may be more severe	Usually <20 min	Same as angina, with decreasing tolerance for exertion or at rest	Similar to stable angina but may be pronounced; transient heart failure can occur
Myocardial infarction	Substernal and may radiate like angina	Heaviness, pressure, burning, constriction	≥30 min but variable	Unrelieved by rest or nitroglycerin	Shortness of breath, sweating, weakness, nausea, vomiting
Pericarditis	Usually begins over sternum or toward cardiac apex and may radiate to neck or left shoulder; often more localized than the pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back	Excruciating, tearing, knifelike	Sudden onset, unrelenting	Usually occurs in setting of hypertension or predisposition, such as Marfan syndrome	Murmur of aortic insufficiency, pulse or blood pressure asymmetry; neurologic deficit
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset; minutes to <1 hr	May be aggravated by breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right ventricular failure, and pulmonary hypertension with large emboli; rales, pleural rub, hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive	Similar to angina	Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension
NONCARDIAC CAUSES					
Pneumonia with pleurisy	Localized over involved area	Pleuritic, localized	Brief or prolonged	Painful breathing	Dyspnea, cough, fever, dull to percussion, bronchial breath sounds, rales, occasional pleural rub
Spontaneous pneumothorax	Unilateral	Sharp, well localized	Sudden onset, lasts many hours	Painful breathing	Dyspnea; hyperresonance and decreased breath and voice sounds over involved lung
Musculoskeletal disorders	Variable	Aching	Short or long duration	Aggravated by movement; history of muscle exertion or injury	Tender to pressure or movement
Herpes zoster	Dermatomal in distribution	Burning, itching	Prolonged	None	Vesicular rash appears in area of discomfort
Esophageal reflux	Substernal, epigastric	Burning, visceral discomfort	10-60 min	Aggravated by large meal, postprandial recumbency; relief with antacid	Water brash
Peptic ulcer	Epigastric, substernal	Visceral burning, aching	Prolonged	Relief with food, antacid	
Gallbladder disease	Epigastric, right upper quadrant	Visceral	Prolonged	May be unprovoked or follow meals	Right upper quadrant tenderness may be present
Anxiety states	Often localized over precordium	Variable; location often moves from place to place	Varies; often fleeting	Situational	Sighing respirations, often chest wall tenderness

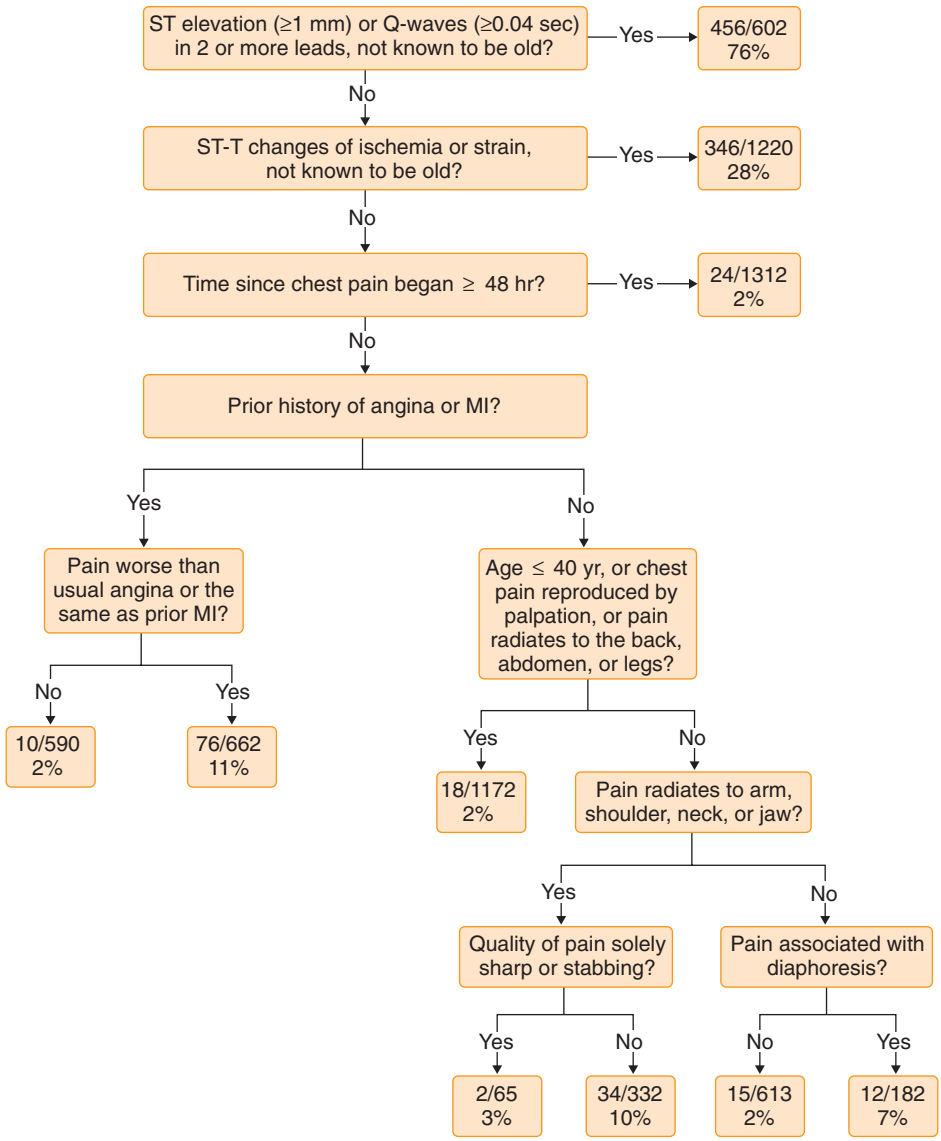

FIGURE 50-1. Flow diagram to estimate the risk for acute myocardial infarction in emergency departments in patients with acute chest pain. For each clinical subset, the numerator is the number of patients with the set of presenting characteristics who had a myocardial infarction; the denominator is the total number of patients presenting with that characteristic or set of characteristics. CHF = congestive heart failure; DVT = deep vein thrombosis. (Modified from Pearson SD, Goldman L, Garcia TB, et al. Physician response to a prediction rule for the triage of emergency department patients with chest pain. *J Gen Intern Med*. 1994;9:241-247.)

TABLE 50-3 COMMON EXERCISE TEST PROTOCOLS*

PROTOCOL	STAGE	DURATION (min)	GRADE (%)	RATE (mph)	METABOLIC EQUIVALENTS AT COMPLETION	FUNCTIONAL CLASS
Modified Bruce protocol†	1	3	0	1.7	2.5	III
	2	3	10	1.7	5	II
	3	3	12	2.5	7	I
	4	3	14	3.4	10	I
	5	3	16	4.2	13	I
Naughton protocol‡	0	2	0	2	2	III
	1	2	3.5	2	3	III
	2	2	7	2	4	III
	3	2	10.5	2	5	II
	4	2	14	2	6	II
	5	2	17.5	2	7	I

*Ramp protocols in which the workload is gradually increased on the basis of the patient's estimated functional capacity to achieve maximal effort in approximately 10 minutes are also useful.
†Commonly used in ambulatory patients.
‡Commonly used in patients with recent myocardial infarction, unstable angina, or other conditions that are expected to limit exercise.
Modified from Braunwald E, Goldman L, eds. *Primary Cardiology*, 2nd ed. Philadelphia: WB Saunders; 2003.

TABLE 50-4 AMERICAN HEART ASSOCIATION/AMERICAN COLLEGE OF CARDIOLOGY GUIDELINES FOR USE OF DIAGNOSTIC TESTS IN PATIENTS WITH PALPITATIONS*

AMBULATORY ELECTROCARDIOGRAPHY	
Class I	Palpitations, syncope, dizziness
Class II	Shortness of breath, chest pain, or fatigue (not otherwise explained, episodic, and strongly suggestive of an arrhythmia as the cause because of a relation of the symptom with palpitation)
Class III	Symptoms not reasonably expected to be due to arrhythmia
ELECTROPHYSIOLOGIC STUDY	
Class I	Patients with palpitations who have a pulse rate documented by medical personnel as inappropriately rapid and in whom electrocardiographic recordings fail to document the cause of the palpitations Patients with palpitations preceding a syncopal episode
Class II	Patients with clinically significant palpitations, suspected to be of cardiac origin, in whom symptoms are sporadic and cannot be documented; studies are performed to determine the mechanisms of arrhythmias, to direct or provide therapy or to assess prognosis
Class III	Patients with palpitations documented to be due to extracardiac causes (e.g., hyperthyroidism)
ECHOCARDIOGRAPHY	
Class I	Arrhythmias with evidence of heart disease Family history of genetic disorder associated with arrhythmias
Class II	Arrhythmias commonly associated with, but without evidence of, heart disease Atrial fibrillation or flutter
Class III	Palpitations without evidence of arrhythmias Minor arrhythmias without evidence of heart disease

*Class I, general agreement the test is useful and indicated; class II, frequently used, but there is a divergence of opinion with respect to its utility; class III, general agreement the test is not useful.
From Braunwald E, Goldman L, eds. *Primary Cardiology*, 2nd ed. Philadelphia: WB Saunders; 2003:132.

TABLE 50-5 A COMPARISON OF THREE METHODS OF ASSESSING CARDIOVASCULAR DISABILITY

CLASS	NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION	CANADIAN CARDIOVASCULAR SOCIETY FUNCTIONAL CLASSIFICATION	SPECIFIC ACTIVITY SCALE
I	Patients with cardiac disease but without resulting limitations of physical activity Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina with strenuous or rapid or prolonged exertion at work or recreation	Patients can perform to completion any activity requiring ≥7 metabolic equivalents, e.g., can carry 24 lb up 8 steps; carry objects that weigh 80 lb; do outdoor work (shovel snow, spade soil); do recreational activities (skiing, basketball, squash, handball, jog or walk 5 mph)
II	Patients with cardiac disease resulting in slight limitation of physical activity They are comfortable at rest. Ordinary physical activity results in fatigue, palpitations, dyspnea, or anginal pain.	Slight limitation of ordinary activity Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening Walking >2 blocks on the level and climbing >1 flight of ordinary stairs at a normal pace and in normal conditions	Patient can perform to completion any activity requiring ≥5 metabolic equivalents but cannot and does not perform to completion activities requiring ≥7 metabolic equivalents, e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance foxtrot, walk at 4 mph on level ground
III	Patients with cardiac disease resulting in marked limitation of physical activity They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.	Marked limitation of ordinary physical activity Walking 1 or 2 blocks on the level and climbing >1 flight in normal conditions	Patient can perform to completion any activity requiring ≥2 metabolic equivalents but cannot and does not perform to completion any activities requiring ≥5 metabolic equivalents, e.g., shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping
IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest	Patient cannot or does not perform to completion activities requiring ≥2 metabolic equivalents; cannot carry out activities listed above (Specific Activity Scale, class III)

From Goldman L, Hashimoto B, Cook EF, et al. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale. *Circulation.* 1981;64:1227-1234. Reproduced by permission of the American Heart Association.

syncope. When the history, physical examination, and ECG do not provide helpful diagnostic information that points toward a specific cause of syncope, it is imperative that patients with heart disease or an abnormal ECG be tested with continuous ambulatory ECG monitoring to diagnose a possible arrhythmia (see Fig. 62-1 in Chapter 62); in selected patients, formal electrophysiologic testing may be indicated (Chapter 62). In patients with no evident heart disease, tilt testing (Chapter 62) can help detect reflex-mediated vasomotor instability.

Other Symptoms

Nonproductive *cough* (Chapter 83), especially a persistent cough (see Fig. 83-1 in Chapter 83), can be an early manifestation of elevated pulmonary venous pressure and otherwise unsuspected heart failure. *Fatigue* and *weakness* are common accompaniments of advanced cardiac disease and reflect an inability to perform normal activities. A variety of approaches have been used to classify the severity of cardiac limitations, ranging from class I (little or no limitation) to class IV (severe limitation) (Table 50-5). *Hemoptysis*

(Chapter 83) is a classic presenting finding in patients with pulmonary embolism, but it is also common in patients with mitral stenosis, pulmonary edema, pulmonary infections, and malignant neoplasms (see Table 83-5 in Chapter 83). *Claudication,* which is pain in the extremities with exertion, should alert the physician to possible peripheral arterial disease (Chapters 79 and 80).

Complete Medical History

The complete medical history should include a thorough review of systems, family history, social history, and past medical history (Chapter 14). The review of systems may reveal other symptoms that suggest a systemic disease as the cause of any cardiovascular problems. The family history should focus on premature atherosclerosis or evidence of familial abnormalities, such as may be found with various causes of the long QT syndrome (Chapter 65) or hypertrophic cardiomyopathy (Chapter 60).

The social history should include specific questioning about cigarette smoking, alcohol intake, and use of illicit drugs. The past medical history may reveal prior conditions or medications that suggest systemic diseases, ranging from chronic obstructive pulmonary disease, which may explain a complaint of dyspnea, to hemochromatosis, which may be a cause of restrictive cardiomyopathy. A careful history to inquire about recent dental work or other procedures is crucial if bacterial endocarditis is part of the differential diagnosis.

PHYSICAL EXAMINATION FOR DETECTION OF SIGNS OF CARDIOVASCULAR DISEASE

The cardiovascular physical examination, which is a subset of the complete physical examination, provides important clues to the diagnosis of asymptomatic and symptomatic cardiac disease and may reveal cardiovascular manifestations of noncardiovascular diseases. The cardiovascular physical examination begins with careful measurement of the pulse and blood pressure (Chapter 7). If aortic dissection (Chapter 78) is a consideration, blood pressure should be measured in both arms and, preferably, in at least one leg. When coarctation of the aorta is suspected (Chapter 69), blood pressure must be measured in at least one leg and in the arms. Discrepancies in blood pressure between the two arms also can be caused by atherosclerotic disease of the great vessels. Pulsus paradoxus, which is more than the usual 10 mm Hg drop in systolic blood pressure during inspiration, is typical of pericardial tamponade (Chapter 77).

General Appearance

The respiratory rate may be increased in patients with heart failure. Patients with pulmonary edema are usually markedly tachypneic and may have labored breathing. Patients with advanced heart failure may have Cheyne-Stokes respirations.

Systemic diseases, such as hyperthyroidism (Chapter 233), hypothyroidism (Chapter 233), rheumatoid arthritis (Chapter 272), scleroderma (Chapter 275), and hemochromatosis (Chapter 219), may be suspected from the patient's general appearance. Marfan syndrome (Chapter 268), Turner's syndrome (Chapter 243), Down syndrome (Chapter 40), and a variety of congenital anomalies also may be readily apparent.

Ophthalmologic Examination

Examination of the fundi may show diabetic (see Fig. 431-24 in Chapter 431) or hypertensive retinopathy (see Fig. 67-11 in Chapter 67) or Roth's spots (see Fig. 431-28 in Chapter 431) typical of infectious endocarditis. Beading of the retinal arteries is typical of severe hypercholesterolemia. Osteogenesis imperfecta, which is associated with blue sclerae, also is associated with aortic dilation and mitral valve prolapse. Retinal artery occlusion (see Fig. 431-29 in Chapter 431) may be caused by an embolus from clot in the left atrium or left ventricle, a left atrial myxoma, or atherosclerotic debris from the great vessels. Hyperthyroidism may present with exophthalmos and typical stare (see Fig. 431-6 in Chapter 431), whereas myotonic dystrophy, which is associated with atrioventricular block and arrhythmia, often is associated with ptosis and an expressionless face (see Fig. 429-2 in Chapter 429).

Jugular Veins

The external jugular veins help in assessment of mean right atrial pressure, which normally varies between 5 and 10 cm H_2O; the height (in centimeters) of the central venous pressure is measured by adding 5 cm to the height of the observed jugular venous distention above the sternal angle of Louis (Fig. 50-2). The normal jugular venous pulse, best seen in the internal jugular vein (and not seen in the external jugular vein unless insufficiency of the jugular venous valves is present), includes an *a* wave, caused by right atrial contraction; a *c* wave, reflecting carotid artery pulsation; an *x* descent; a *v* wave, which corresponds to isovolumetric right ventricular contraction and is more marked in the presence of tricuspid insufficiency; and a *y* descent, which occurs as the tricuspid valve opens and ventricular filling begins (Fig. 50-3). Abnormalities of the jugular venous pressure (Fig. 50-4) and arterial pulse are useful in detecting conditions such as heart failure, pericardial disease, tricuspid valve disease, and pulmonary hypertension (Table 50-6).

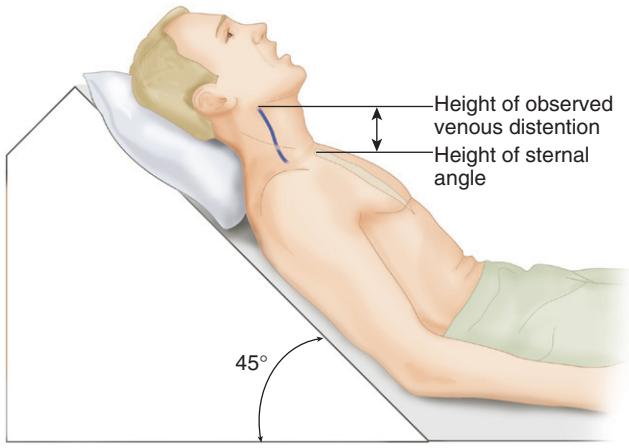

FIGURE 50-2. Jugular venous distention is defined by engorgement of the internal jugular vein more than 5 cm above the sternal angle at 45 degrees. The central venous pressure is the observed venous distention above the sternal angle plus 5 cm. (From American Academy of Family Physicians Online. http://www.aafp.org/afp/20000301/1319.html. Accessed June 9, 2010.)

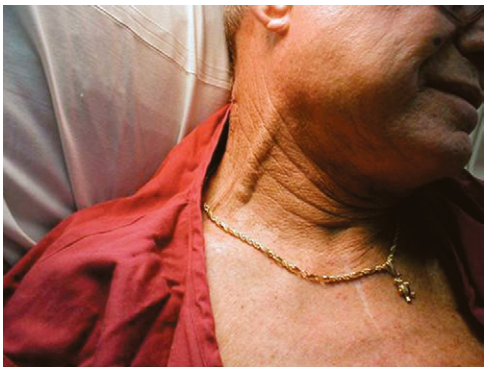

FIGURE 50-3. Typical distention of the internal jugular vein. (From http://courses.cvcc.vccs.edu/WisemanD/jugular_vein_distention.htm.)

Carotid Pulse

The carotid pulse should be examined in terms of its volume and contour. The carotid pulse (Fig. 50-5) may be increased in frequency and may be more intense than normal in patients with a higher stroke volume secondary to aortic regurgitation, arteriovenous fistula, hyperthyroidism, fever, or anemia. In aortic regurgitation or arteriovenous fistula, the pulse may have a bisferious quality. The carotid upstroke is delayed in patients with valvular aortic stenosis (Chapter 75) and has a normal contour but diminished amplitude in any cause of reduced stroke volume.

Cardiac Inspection and Palpation

Inspection of the precordium may reveal the hyperinflation of obstructive lung disease or unilateral asymmetry of the left side of the chest because of right ventricular hypertrophy before puberty. Palpation may be performed with the patient either supine or in the left lateral decubitus position; the latter position moves the left ventricular apex closer to the chest wall and increases the ability to palpate the point of maximal impulse and other

phenomena. Low-frequency phenomena, such as systolic heaves or lifts from the left ventricle (at the cardiac apex) or right ventricle (parasternal in the third or fourth intercostal space), are felt best with the heel of the palm. With the patient in the left lateral decubitus position, this technique also may allow palpation of an S_3 gallop in cases of advanced heart failure or an S_4 gallop in cases of poor left ventricular distensibility during diastole. The left ventricular apex is more diffuse and sometimes may be frankly dyskinetic in patients with advanced heart disease. The distal palm is best for feeling thrills, which are the tactile equivalent of cardiac murmurs. By definition, a thrill denotes a murmur of grade 4/6 or louder. Higher-frequency events may be felt best with the fingertips; examples include the opening snap of mitral stenosis or the loud pulmonic second sound of pulmonary hypertension.

Auscultation

The first heart sound (Fig. 50-6), which is largely produced by closure of the mitral and—to a lesser extent—the tricuspid valves, may be louder in patients with mitral valve stenosis and intact valve leaflet movement and less audible in patients with poor closure due to mitral regurgitation (Chapter 75). The second heart sound is caused primarily by closure of the aortic valve, but closure of the pulmonic valve is also commonly audible. In normal individuals, the louder aortic closure sound occurs first, followed by pulmonic closure. With expiration, the two sounds are virtually superimposed. With inspiration, by comparison, the increased stroke volume of the right ventricle commonly leads to a discernible splitting of the second sound. This splitting may be fixed in patients with an atrial septal defect (Chapter 69) or a right bundle

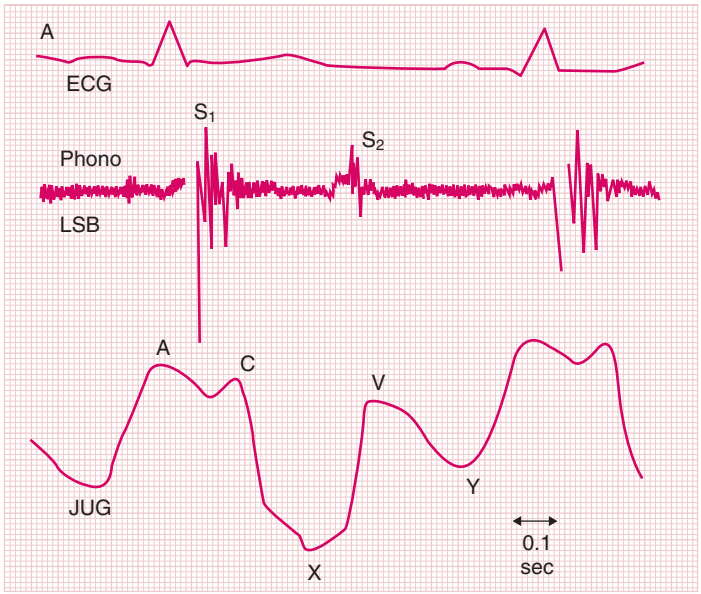

FIGURE 50-4. Normal jugular venous pulse. ECG = electrocardiogram; JUG = jugular vein; LSB = left sternal border; phono = phonocardiogram; S_1 = first heart sound; S_2 = second heart sound.

TABLE 50-6 ABNORMALITIES OF VENOUS PRESSURE AND PULSE AND THEIR CLINICAL SIGNIFICANCE

Positive hepatojugular reflux	Suspect heart failure, particularly left ventricular systolic dysfunction (echocardiography recommended)
Elevated systemic venous pressure without obvious *x* or *y* descent, quiet precordium, and pulsus paradoxus	Suspect cardiac tamponade (echocardiography recommended)
Elevated systemic venous pressure with sharp *y* descent, Kussmaul's sign, and quiet precordium	Suspect constrictive pericarditis (cardiac catheterization and MRI or CT recommended)
Elevated systemic venous pressure with a sharp brief *y* descent, Kussmaul's sign, and evidence of pulmonary hypertension and tricuspid regurgitation	Suspect restrictive cardiomyopathy (cardiac catheterization and MRI or CT recommended)
A prominent *a* wave with or without elevation of mean systemic venous pressure	Exclude tricuspid stenosis, right ventricular hypertrophy due to pulmonary stenosis, and pulmonary hypertension (echo-Doppler study recommended)
A prominent *v* wave with a sharp *y* descent	Suspect tricuspid regurgitation (echo-Doppler or cardiac catheterization to determine etiology)

CT = computed tomography; MRI = magnetic resonance imaging.
From Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine*, 5th ed. Philadelphia: WB Saunders; 1997.

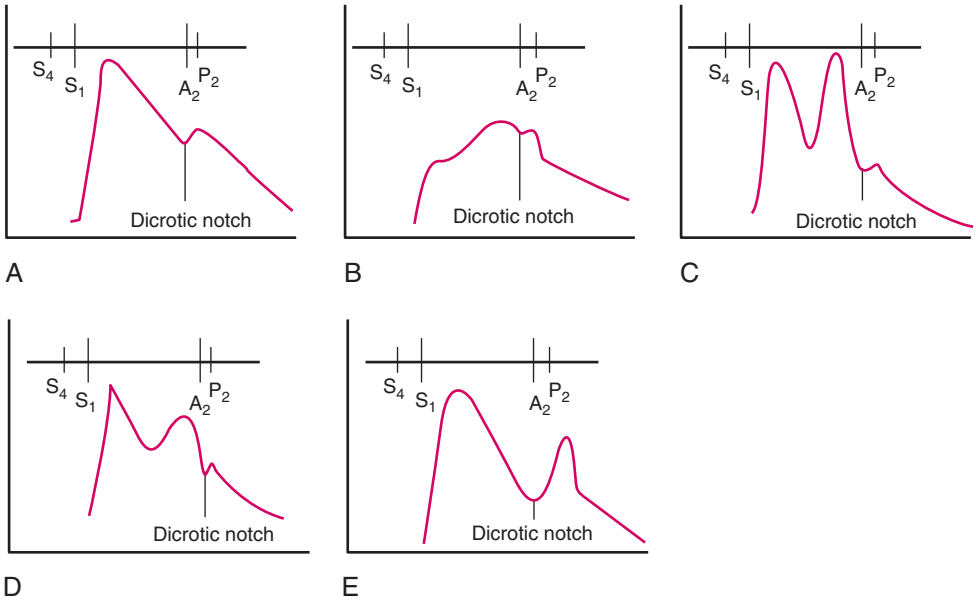

FIGURE 50-5. Schematic diagrams of the configurational changes in the carotid pulse and their differential diagnosis. Heart sounds also are illustrated. **A,** Normal. **B,** Anacrotic pulse with slow initial upstroke. The peak is close to the second heart sound. These features suggest fixed left ventricular outflow obstruction, such as valvular aortic stenosis. **C,** Pulsus bisferiens, with percussion and tidal waves occurring during systole. This type of carotid pulse contour is observed most frequently in patients with hemodynamically significant aortic regurgitation or combined aortic stenosis and regurgitation with dominant regurgitation. It rarely is observed in patients with mitral valve prolapse or in normal individuals. **D,** Pulsus bisferiens in hypertrophic obstructive cardiomyopathy. This finding rarely is appreciated at the bedside by palpation. **E,** Dicrotic pulse results from an accentuated dicrotic wave and tends to occur in sepsis, severe heart failure, hypovolemic shock, and cardiac tamponade and after aortic valve replacement. A_2 = aortic component of the second heart sound; P_2 = pulmonary component of the second heart sound); S_1 = first heart sound; S_4 = atrial sounds. (From Chatterjee K. Bedside evaluation of the heart: the physical examination. In: Chatterjee K, Chetlin MD, Karliner J, et al, eds. *Cardiology: An Illustrated Text/Reference*. Philadelphia: JB Lippincott; 1991:3.11-3.51.)

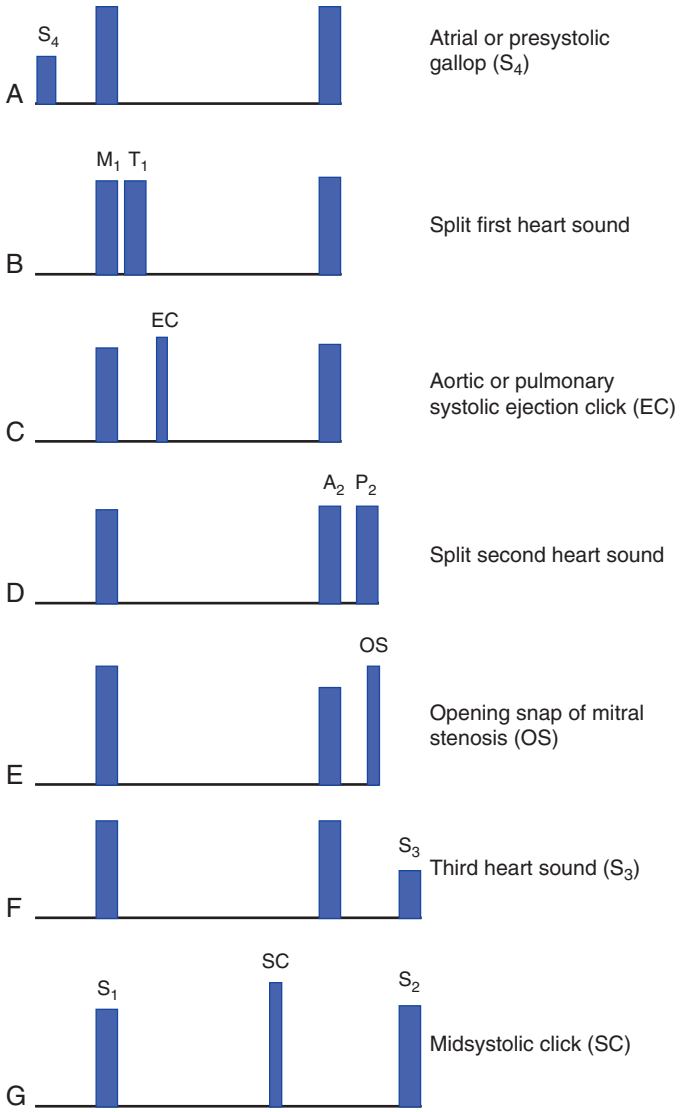

FIGURE 50-6. Timing of the different heart sounds and added sounds. (Modified from Wood P. *Diseases of the Heart and Circulation*, 3rd ed. Philadelphia: JB Lippincott; 1968.)

branch block. The split may be paradoxical in patients with left bundle branch block or other causes of delayed left ventricular emptying. The aortic component of the second sound is increased in intensity in the presence of systemic hypertension and decreased in intensity in patients with aortic stenosis. The pulmonic second sound is increased in the presence of pulmonary hypertension.

Early systolic ejection sounds are related to forceful opening of the aortic or pulmonic valve. These sounds are common in congenital aortic stenosis, with a mobile valve; in hypertension, with forceful opening of the aortic valve; and in healthy young individuals, especially when cardiac output is increased. Midsystolic or late systolic clicks are caused most commonly by mitral valve prolapse (Chapter 75). Clicks are relatively high-frequency sounds that are heard best with the diaphragm of the stethoscope.

An S_3 corresponds to rapid ventricular filling during early diastole. It may occur in normal children and young adults, especially if stroke volume is increased. After about 40 years of age, however, an S_3 should be considered abnormal; it is caused by conditions that increase the volume of ventricular filling during early diastole (e.g., mitral regurgitation) or that increase pressure in early diastole (e.g., advanced heart failure). A left ventricular S_3 gallop is heard best at the apex, whereas the right ventricular S_3 gallop is heard best at the fourth intercostal space at the left parasternal border; both are heard best with the bell of the stethoscope. An S_4 is heard rarely in young individuals but is common in adults older than 40 or 50 years because of reduced ventricular compliance during atrial contraction; it is a nearly ubiquitous finding in patients with hypertension, heart failure, or ischemic heart disease.

The opening snap of mitral and, less commonly, tricuspid stenosis (Chapter 75) occurs at the beginning of mechanical diastole, before the onset of the rapid phase of ventricular filling. An opening snap is high pitched and is heard best with the diaphragm; this differential frequency should help distinguish an opening snap from an S_3 on physical examination. An opening snap commonly can be distinguished from a loud pulmonic component of the second heart sound by the differential location (mitral opening snap at the apex, tricuspid opening snap at the left third or fourth intercostal space, pulmonic second sound at the left second intercostal space) and by the longer interval between S_2 and the opening snap.

Heart murmurs may be classified as systolic, diastolic, or continuous (Table 50-7). Murmurs are graded by intensity on a scale of 1 to 6. Grade 1 is faint and appreciated only by careful auscultation; grade 2, readily audible; grade 3, moderately loud; grade 4, loud and associated with a palpable thrill; grade 5, loud and audible with the stethoscope only partially placed on the chest; and grade 6, loud enough to be heard without the stethoscope on the chest. Systolic ejection murmurs usually peak in early to mid systole when left ventricular ejection is maximal; examples include fixed valvular, supravalvular, or infravalvular aortic stenosis and pulmonic stenosis. The murmur of hypertrophic obstructive cardiomyopathy has a similar ejection quality, although its peak may be later in systole when dynamic obstruction is maximal (Chapter 60). Pansystolic murmurs are characteristic of mitral or tricuspid regurgitation or with a left-to-right shunt from conditions such as a ventricular septal defect (left ventricle to right ventricle). A late systolic murmur is characteristic of mitral valve prolapse (Chapter 75) or ischemic papillary muscle dysfunction. Ejection quality murmurs also may be heard in patients with normal valves but increased flow, such as occurs with marked anemia, fever, or bradycardia secondary to congenital complete heart block; they also may be heard across a valve that is downstream from increased flow because of an intracardiac shunt. Maneuvers such as inspiration, expiration, standing, squatting, and hand gripping can be especially useful in the differential diagnosis of a murmur; however, echocardiography commonly is required to make a definitive diagnosis of cause and severity (Table 50-8).

High-frequency, early diastolic murmurs are typical of aortic regurgitation and pulmonic regurgitation from a variety of causes. The murmurs of mitral and tricuspid stenosis begin in early to mid-diastole and tend to diminish in intensity later in diastole in the absence of effective atrial contraction, but they tend to increase in intensity in later diastole if effective atrial contraction is present.

Continuous murmurs may be caused by any abnormality that is associated with a pressure gradient in systole and diastole. Examples include a patent ductus arteriosus, ruptured sinus of Valsalva aneurysm, arteriovenous fistula (of the coronary artery, pulmonary artery, or thoracic artery), and a mammary soufflé. In some situations, murmurs of two coexistent conditions (e.g., aortic stenosis and regurgitation; atrial septal defect with a large shunt and resulting flow murmurs of relative mitral and pulmonic stenosis) may mimic a continuous murmur.

Abdomen
